The headquarters of the Institute are in Margaret Street, W., in a building known as the Parkes' Museum, so-called to commemorate the celebrated Hygienist of that name. The whole purpose of this museum is to serve as a means of practical demonstration for the diffusion of knowledge in sanitary science, and at the present day it undoubtedly forms the best collection in Great Britain of all the various apparatus and material which can be claimed to have any connection with the public health. The value of such an institution does not need insistence upon here; but the remarks of the chairman, Sir Douglas Galton, in his recent address, may be aptly reproduced. "The evils," he says, "of our congested population meet us at every turn. If our progenitors had been properly educated in sanitary matters, our towns would not have been allowed to contain unhealthy localities, houses would not have been permitted to be built on damp unhealthy sites, buildings would not have been constructed so as to impede the circulation of air and incidence of light. Our town populations would not have been allowed to grow up herded together like the beasts of the field, without moral training or self-restraint, and our country population would not have been allowed to destroy the healthy conditions which surround them, by vitiating the pure air, and by contaminating the springs of pure water. The Sanitary Institute is thus the direct outgrowth of the public need for sanitary education."

An excellent descriptive catalogue of the contents of the museum has recently been compiled, and those only among the 11,500 persons who have visited the building during the year ending March, 1892, who were acquainted with the museum so recently as eighteen months ago, can appreciate at its true worth the value of this addition, and can adequately testify to the improvement in the arrangement and grouping of the various sanitary appliances which has also been effected. This catalogue is bound up with the last volume of "Transactions," which, in addition, includes a lengthy list of Fellows, Members, and Associates of the Institute, a list of the contributions to the very valuable library during 1891, a very full report of valuable and able papers of hygienic interest, which have been read by Dr. Louis Parkes, Mr. Grantham, Prof. Wynter Blyth, and Sir Douglas Galton. The volume also contains a copy of the Annual Report of the Council, and a glimpse of this gives one a capital insight into the scope and work of the Institute.

In the lecture room, in addition to papers such as those referred to above, a systematic course of lectures for sanitary officers is given throughout the year by a staff of exceptionally capable lecturers, including as it does such gentlemen as Sir Douglas Galton, Prof. Corfield, Dr. Louis Parkes, Mr. Shirley Murphy, Prof. Wynter Blyth, Prof. H. Robinson, &c. That the worth of these lectures is appreciated is sufficiently exemplified by the fact that 161 students attended them during the year, nor are they lacking attractions similar to that which insured the constant attendance of young Mr. Parker at the village choir-meetings, for they are regularly patronized by one or two female devotees of the Goddess Hygeia. There are, however, lectures provided entirely for ladies by Dr. A. T. Schofield, who treated the following subjects in his last course—

"The Domestic Treatment of Disease"

"Microbes"

"Physical Culture"

"The Care of Old Age"

These have been well attended, and the Duchess of Albany recently presented the prizes gained by those who emerged successfully from a competitive class examination upon these subjects. The Institute holds examinations twice yearly for inspectors of nuisances and local surveyors. At these examinations 361 candidates presented themselves during the year, and 246 received "certificates of competency." Both lectures and examinations are now being provided in several large provincial towns, at a great saving of expense and trouble to aspirants for the "certificate of competency," and with the apparent effect of considerably stimulating local interest in sanitary matters. Finally, the annual Health Congress held under the auspices of the Institute is always an instructive and interesting feature in its proceedings, and is largely attended and much appreciated.

#### OUR BOOK SHELF

*Cooley's Cyclopædia of Practical Receipts* By W. North, M.A. Camb., F.C.S. Seventh Edition, revised and greatly enlarged (London J. and A. Churchill, 1892)

THIS work is intended as a general book of reference for manufacturers, tradesmen, amateurs, and heads of families,

and contains information upon all sorts of subjects, from a list of abbreviations usually employed in writing, to a description of the rare metal zirconium. Between these two articles we find notices of the methods of brewing, and the proper way of laying bricks and ventilating houses, the nature and treatment of broken wind in horses, the composition of digestive, aperient, and tonic pills, the practice of photography, the nature of infective diseases in man and beast, the destruction of caterpillars in plants, the best kind of clothes to wear, and the method of taking grease spots out of clothing. From these samples of the contents it will be seen that the book is really a most extraordinary work of reference and one which is not likely to lie idle on the shelves, but to be more or less in constant use. The work of revision has evidently been carefully done, and must have been one of no small labour, as it has been brought well up to date and many articles must be entirely new. The great practical utility of the work is shown by the large circulation it has enjoyed for many years, and the editor has done his best to maintain the well-deserved reputation of the book.

*Traité Encyclopédique de Photographie* First Supplement A. Par Charles Fabre (Gauthier-Villars et Fils, 1892)

MANY of our readers are already thoroughly acquainted with this excellent treatise which we owe to M. Fabre. In the present volume we have the first of the series of supplements which will be issued in order to keep the book well up to date. The range of progress here shown is that accomplished during the years 1889-92. The same arrangement as to numbering the paragraphs is still presented, so that it will be quite easy for those having the original volumes to refer to any section in this supplement.

The matter which is chiefly treated of here refers to the various properties and kinds of lenses and to their combinations—thus some of the most important headings that have been considerably developed may be stated as follows:—Methods of measuring focal distances, Martin's objectives, simple objectives, calculation of objectives, rapid eyescopes, Zeiss' objectives, &c. Many other new discoveries, such as Lippmann's photography in colours, have also received attention.

With these supplements this encyclopedia will be found to be greatly enhanced in value, for at the present day photography is undergoing many and rapid changes the recording of which in this form is no light task.

### LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

#### The Mustakh Exploration

MR CONWAY'S march from our newly acquired district of Hunza into Baliautan (reported in the *Times*), up the Hisper glacier on one side and down the Bialo on the other to Askolay, is a splendid feat to have accomplished, a memorable achievement, and his account of it will be something to look forward to on his return to England. The total length of these two glaciers is certainly something between sixty and seventy miles measured upon the map, and over this distance the glacial forces in action are on the grandest scale. The view obtained of the Hisper glacier from the two points we ascended on either side of the Nushik La is hardly to be described, from thence the end of the Hisper glacier is not defined, and could only be indicated from the run of the spurs on the north side of the valley, and what information the guides could give. This made the total length sixty four miles. By traversing this length of the two glaciers Mr Conway has been able to get into ground

never before visited, viz., that great ice field on the main range of the Mustakh, the full extent of which is quite unknown, and from which the Nobundi Sobundi branch of the Panmah glaciers also descends. Most interesting will it be to read the account of this glacial area from the pen of a man who knows the Alps so well, and has ascended so many of its peaks. He has gone direct and fresh from the one to the other—what an exquisite treat—and he has now seen glacial action on the vastest scale it is presented at the present time in a mountain chain out of Polar latitudes. My experience was the reverse of this, for I had not the opportunity of seeing an Alpine glacier until twenty years after I had been surveying those on the Yarkund and Hunza frontiers, and in the interval the vividness of their aspects and minor details had much faded. It is to be hoped that Mr Conway has with him, and used, a plane table, properly projected on the four miles to the inch scale, with all the peaks fixed by the Trigonometrical Survey of India, correctly plotted on it, and will thus be enabled to add to and correct much of the previous reconnaissance work. There is no doubt, had Capt. Younghusband, who was another late explorer in this part of the world, worked with a plane table along his line of route towards Hunza, the results of his exploration would have been of tenfold value, and far more extended. The Indian Government should make it a rule that all officers permitted or selected to explore the unsurveyed territory beyond our Indian frontier, should, as a preliminary training, do a season's work plane tabling with a Himalayan survey party. It would also be an admirable training for officers selected for the Quartermaster General's and Intelligence Departments.

#### Nebular Spectrum of Nova Aurigæ

NOVA AURIGÆ faded away so steadily in March and April as to give little promise of soon again attaining any considerable brightness. All the more startling, therefore, was Mr Espin's announcement of Mr Corder's discovery that it had reappeared and that he himself on August 21 had seen it as a star of the 9.2 magnitude with a monochromatic spectrum, presumably about 500 mmm in wave length.

Fortunately the 15 inch refractor of this Observatory is still in working order, and still more fortunately my old colleague in the observation of Nova Cygni, Mr I. G. Lohse, is staying here. On August 25 and 26 we were able to examine the Nova with a compound prism in the Grubb stellar spectroscope. The spectrum thus seen evidently contained two bright lines, the positions of which we determined as follows:—

Chief Line Brightness 5 to 10			
Date	Wave length	Measures	Observer
Aug 25	500.4	4	R. C.
26	500.4	3	"
25	500.5	3	J. G. L.
26	499.9	5	"

Second Line Brightness 1			
Date	Wave length	Measures	Observer
Aug 25	495.3	2	R. C.
26	494.6	3	"
25	495.9	3	J. G. L.
26	495.4	5	"

From these we may derive the mean values of 500.3 and 495.3, which prove, as we think beyond doubt, that Nova Aurigæ is now mainly shining as a luminous gas nebula.

Once or twice on the 25th August, at the best moments, I had noticed feeble traces of a condensed luminosity in the spectroscope, far away on the side of less refrangibility. Our time, however, was fully occupied in observing the two brighter lines and the zinc lead spectrum, with which we compared them, until daylight prevented further observation. On the 26th, haze and bad definition concealed everything but the chief lines, but on the very clear night of the 28th, continuing the observations alone, I examined the star with a power of 229 on the wire micrometer, and wishing to see if the spectrum had materially altered I viewed the star through an excellent direct-vision prism. In this way I at once saw a faint continuous spectrum in the green, together with a distinct line in the yellow. With the spectroscope the line was also readily perceived, but not having prepared the battery for the illuminations and comparisons, no reliable direct measures could be made. By introducing

the D line into the instrument, however, I found the stellar line to be distant from it towards the violet by a quantity equal to the interval between the nebular lines. This gives a wavelength of 5801, which agrees closely with a bright line in Nova Cygni, in the Wolf-Rayet stars, and in  $\gamma$  Argus (compare *Copernicus*, ii p 112, and iii pp 205 and 206). The continuous spectrum seemed to begin somewhat suddenly at 5694, and faded away about 540.

On each night of observation the star was about 9.6 magnitude.

Dunecht, September 6

### Daytime Seeing at the Lick Observatory

To some of the readers of NATURE it may be a matter of considerable surprise, as it certainly was to the writer, to find the marked superiority which a small telescope sometimes offers over a large one for the observation of solar prominences.

On numerous occasions during the last year, while adjusting the large star spectroscope of this observatory to the 36-inch refractor, I have improved the opportunity to examine the limb of the sun with a Rowland grating. At no time, however, has it been possible to get any definition in prominence. With the 6-inch equatorial, on the contrary, one gets very fair definition, even in the middle of the day, while in the early morning, from six to eight o'clock, the seeing is, as a rule, superb. Thinking these differences might possibly vanish if the larger glass were used earlier in the morning, I have recently made a systematic comparison of the three equatorials, viz. the 6-inch, the 12-inch, and the 36-inch. For this purpose a small grating spectroscope (kindly loaned by the Chabot Observatory) was used with an adapter which fitted all three telescopes, so that the whole comparison could be made in a few minutes. The third and fourth orders of a 14338-line grating were employed.

The result of a half-dozen mornings' observations was that no detail whatever could be made out with the 36-inch, however much care one might use in the adjustment of his instrument. One could form a rough estimate of the height and general outline of the prominence, but nothing more.

On the 12-inch the general features were considerably more distinct, but the fine delicate tracings of the various parts of the prominence could be seen only with the 6-inch. The capping down of the 36-inch and the 12-inch failed utterly, as might have been expected, to improve the definition on any occasion.

The large image of the sun given by the 36-inch (six inches in diameter), combined with the poor seeing during the daytime, makes the instrument act, for sunspot observation, very much like an integrating spectroscope. The lines affected by absorption, in spots of any considerable size, can be picked out readily, but one finds it quite impossible to compare the absorption of the nucleus with that of the penumbra. These three telescopes each give images of nearly the same brightness, and one does not find much, if any, difference in the amount of dispersed light in the field.

During the dry season, the sides of the cañons surrounding this observatory become intensely hot, and highly heated currents of air are continually rising from them. So that, probably, the conditions which make the order of efficiency of these telescopes in the daytime just the reverse of what it is at night, are purely local.

HENRY CREW

Lick Observatory, August 19

### Ridgway on the Humming-birds

MR ROBERT RIDGWAY, curator of the bird department of the U. S. National Museum, has just published (in separate form), in the report of that institution for 1890, his monograph of the Trochilidae. Coming from such an authority and essaying to deal with such an interesting group, this work will undoubtedly command the attention of ornithologists, and be studied with the care it no doubt merits. It makes its appearance in octavo form, of some 130 pages, being illustrated by 46 full-page plates, and has besides a number of cuts in the text. The plates give us many species of humming-birds and their nests, they being all of the "electro-process" variety, and chiefly copied from Gould's princely work upon the Trochilidae. As is usually the case, most of the figures given have suffered by the method of reproduction employed, and not being coloured, they offer us, at the

best, with but a poor idea of the "living gems" they are supposed to portray. With more or less thoroughness Mr Ridgway has touched upon the early history and the literature of his subject, upon the geographical distribution of the various species, upon their number, which he makes out to be about 500, upon their natural history in general (treated in various brief sections), and there are descriptions of their external characters and a short note upon a few of their internal ones. It is with the statements made in the latter that I chiefly propose to deal in the present connection, and, aware as I am of our author's knowledge of the literature of what we may call the natural history and classification of the humming-birds, as contra distinguished from their morphology and affinities, I must confess my surprise at his ignorance of the latter part of his subject. Mr Ridgway remarks (p. 290) that "the humming-birds possess nothing absolutely peculiar, although certain features, shared by other groups of birds, notably the swifts (*Micropteryx*), are developed to an extreme degree, as, for example, the very high keel to the sternum and consequent excessive development of the pectoral muscles, the short armwing (humerus) and extremely long handwing (manus), and minute feet with relatively large, strongly curved, and sharp claws. The humming-birds and swifts further agree in numerous anatomical characters, and there can be no doubt that they are more closely related to each other than are either to any other group of birds. In fact, except in the shape of the bill and structure of the bones of the face, the humming-birds and swifts present no definite differences of osteological structure." As the present writer has probably published double the number of accurate figures illustrating the *entire anatomy* of a great many species of humming-birds as compared with any other worker, and, further, has published correct accounts of the same to the extent exceeding that of any three living avian morphologists, and those figures and descriptions having been very extensively accepted as correct, perhaps our author will consider me competent to criticize the statement which I have just quoted from his work. Notwithstanding the extensive and painstaking labour I have given to such matters, I reckon it but as little when compared with the opinions given us by Huxley and Kitchen Parker in the same premises.

As long ago as 1867 (P. Z. S., p. 456), Huxley expressed the view that "in their cranial characters the swifts are far more closely allied with the swallows than with any of the Desmognathous birds, the swift presenting but a very slight modification of the true Passerine type exhibited by the swallow," and Parker has said in *The Zoologist* for March, 1889 (p. 2), "I agree with my friend, Dr. Shufeldt, that the 'swallow and the swift are near akin.' My opinion is not the simple judgment it was forty years ago. I have observed a good many things since then in the structure of birds of all sorts." Both of these high opinions I can confirm, and in support of them, and as contradicting every statement almost that my good friend and ornithologist, Mr Ridgway, has made in his work touching the structure of swifts and humming-birds, I would invite his attention to many comparative figures and accounts published by me in the Proceedings of the Zoological Society of London at various times, and also to an extensive paper of mine which appeared in the Journal of the Linnean Society of London, in 1888 or 1889, having been read at the Society by W. K. Parker, F.R.S., who accepted, in the main, what I had stated in it. Therein I anatomically compare the *entire* structure of every species of United States swallow with the corresponding structures in a great many swifts and a great many humming-birds, and I would invite Mr Ridgway's attention to the synoptical comparisons given on pages 376-378, especially as offsetting his statement, as quoted, that "in fact, except in the shape of the bill and structure of the bones of the face, the humming-birds and swifts present no definite differences of osteological structure." And, unless as a true systematist and believer in *colours and measurements* rather than in structural characters as determining the real affinities of vertebrate forms, I would finally invite his consideration of my comparative figures and description of the humerus of a swallow, a swift, and a humming-bird given in the Proc. Zool. Soc., Lond., for 1887 (pp. 501-503), and then ask his candid opinion upon the question whether the humerus of a swift is morphologically more like that of a humming-bird than it is like that of a swallow, and the humerus is one of the bones that has been so frequently dragged into the discussion to prove cypselo-trochiline affinities.

Washington, D.C., July 24.

R. W. SHUFELDT

### "The Limits of Animal Intelligence"

IT is with much pleasure that I have read Prof Lloyd Morgan's letter, wherein he tells us that "the power of cognizing relations, reflection, and introspection" appears to him to mark a "new departure" in the ascending scale of psychical activities. His term, "feeling of awareness of certain relationships," is new to me, however, and seems to demand a further distinction. I am generally aware, in a vague way, of what I may be doing—that is to say I have a certain consciousness of it. But every now and then I find that I have done, without consciousness, things which I could not have done without the exercise of my sensitive faculty, or without the guidance of bodily movement, by that faculty.

I most cordially concur in the Professor's desire that the investigations to which he refers should be accompanied by "calm, temperate, and impartial discussion" founded on observation and experiment. I, as well as Prof Lloyd Morgan, have long carried on such observations and experiments, and it is on them that are founded what I have written on "Our lower and higher mental powers" in chapters xiv and xv of my book "On Truth." To them I may perhaps be permitted to direct the Professor's attention, since he is engaged with a work on Comparative Psychology. I have as little wish to dogmatize as has Prof Lloyd Morgan, and am perfectly ready and willing to recognize the true rationality of any animal whenever I obtain evidence thereof. My assertion of the exclusive rationality of man has been represented as due to other causes than what I deem to be the weight of scientific evidence. Such is an utter mistake. To admit that animals possess intellect would neither be repugnant to my feelings nor conflict with any other of my convictions. As yet I hold all animals to be irrational, simply because I have met with, in them, nothing inexplicable by what the Professor calls "simple awareness" and what I call related feelings. All prejudice should indeed be eliminated from scientific inquiry, but such can hardly be the case with any one who starts from an *a priori* "stand-point of evolution" in the sense that he holds discontinuities in nature—real "new departures"—to be impossible.

The Professor says: "In conclusion I must be allowed to say that the phrases 'differences in kind' and 'differences in degree' savour somewhat of mere Academic discussion." Nevertheless there really are differences of kind, and such differences are themselves different in kind from mere differences of degree. He would, of course, allow that the difference between the Binomial Theorem and the Bouquet of Chateau d'Yquem is one "of kind," as also that between solving the *Pons asinorum* and riding *Equus asinus*. I am convinced there are also psychical differences of kind, and I have become so convinced (in spite of having started with a contrary opinion) through experiments and observations.

ST GEORGE MIVART

Hurstcote, September 6

### The Theory of the Telephone

IN a paper in this month's *Phil Mag* I ventured to publish an explanation of the fact that in the telephone it is necessary for the diaphragm to be situated in a permanent magnetic field.

Since then my attention has been called to a paper (*The Electrician*, Feb 11, 1887, p. 302) by Mr Oliver Heaviside, in which he has given a very complete theory of the question at issue.

I hasten to express my regret that I had not met with this paper in time.

FRED T TROUTON

Physical Laboratory, Trinity College, Dublin.

### Crater-like Depressions in Glaciers

IN the note on the St. Gervais Catastrophe (*NATURE* of September 1) I read that a crater-like depression had been found in the Tête Rousse Glacier. As such depressions are quite exceptional occurrences in European glaciers, it may be of interest to note that I found several holes of a similar kind in the great Tasman Glacier in New Zealand. One of these reached—like the Tête Rousse one—apparently to the bottom, the others, which were from 150 feet to 300 feet deep, did not. The walls of these "craters" were not vertical but above only 45°, the incline increasing below. Till now I have considered these funnel-shaped depressions as immensely widened "Glacier mills,"

\* Referred to on p. 266 of *NATURE* for July 31, 1892.

but after the observation on the Tête Rousse it seems to me not improbable that these holes on the Tasman were also originally caused by subglacial collapse.

R. VON LENDENFELD

### CHOLERA PREVENTION AND VACCINATION

THE epidemic of cholera with which this country is threatened seems likely to test very completely the means for the prevention of its spread which have been devised as the result of the extended experience of some of the ablest hygienists. The working out of the history of an epidemic disorder must necessarily be extended over a prolonged period of time, for it is dependent on the researches not only of the clinical observer, but of the pathologist and the bacteriologist and of those who devote themselves to the difficult study of the march of epidemics. The development of such researches is closely allied to the advance of science generally, and although there is at any one period a large admixture of "fashion" in the opinions held by experts, yet in time this fades, and the truth is established. It cannot be too clearly stated that the best measures for the prevention of an epidemic disorder can only be devised when we possess an accurate knowledge of the infective agent of the disease (bacillus or not, as the case may be), of its life-history, of its varying degrees of virulence, and the mode of entrance into the body, of the conditions under which it multiplies, and of the changes which it produces in the human body.

In the case of cholera our knowledge is not yet complete. Clinical observers many years ago showed that the infective agent was present in the peculiar evacuations passed by the cholera patient, and it was further found that these evacuations were the means of contaminating the water supply of a locality, and so causing the spread of the disease in the community. These two facts have been established beyond doubt. The exact nature of the living infective agent is not, however, so well ascertained. It was in 1884 that Koch described the *Vibrio Cholera Asiaticus* as constantly present in the evacuations of cholera patients, but he was unable to prove that it was the cause of the disease, owing to the insusceptibility of animals to cholera. It was shown that the vibrio was present also in the intestinal walls, but it was never found in the organs of the body. The work of subsequent observers has brought forward fresh facts of importance. It is now known that the cholera vibrio (the comma bacillus) is allied to several other forms which are pathogenic, and that there are several varieties (perhaps twelve) which have been described by Dr Cunningham. The cholera vibrio is also known to vary greatly in virulence, it is so susceptible to its surroundings that a slight change will diminish its activity and certain conditions will increase its virulence. One method of increasing its activity is by passing it through a series of animals (guinea-pigs), after a certain time the vibrio becomes extremely active and will kill animals very quickly, it is said in even eight hours. With these virulent cultures symptoms have been produced in animals closely resembling those of Asiatic cholera, in the exudation of liquid into the intestines, in the cramps, in the suppression of urine, and in the collapse so well known in the disease in man. There are therefore certain grounds for considering Koch's vibrio as the cause of Asiatic cholera. But the question is not settled. It is not as clear that the vibrio is the cause of Asiatic cholera as that the bacillus anthracis is the cause of anthrax. The probabilities are greatly in favour of this presumption, but the slight doubt existing must be borne in mind when the question of vaccination for cholera is to be considered practically. The doubt that rests on the vibrio as the cause of cholera may be stated shortly in the fact of the existence of allied forms of bacteria which produce similar symptoms, such as the vibrio Metschnikov.

koví. We know, too, that in man cholera is produced by what is drunk, and yet animals fed with the vibrio do not get any of the symptoms which have been mentioned, unless they are "prepared" by a course of treatment, either by neutralizing the acidity of the contents of the stomach, and subsequently giving a dose of opium to quiet the intestines, or by giving a dose of alcohol with the vibrio. This vibrio cannot get through the acid stomach alive. The answer to the question as to how it gets through the human stomach rests partly in the fact that in the early part of digestion, or in between meals, the stomach is not very acid, and so there may not be a sufficient degree of acidity to kill the vibrio. Such remarks would, however, equally apply to the guinea-pig stomach, and the question as to why in animals the swallowed vibrio does not produce choleraic symptoms unless the animal is "prepared" is still unanswered, although such animal may be killed by an injection of the virulent preparation of the vibrio into its veins. This difficult point can only be settled by investigations along new lines, probably chiefly chemical.

One point suggested by the investigations of the cholera vibrio which we surmised previously to 1884, is that the infective agent in the disease not only primarily attacks the intestines, but grows there, producing the symptoms of the disease by its chemical products, without itself entering the blood stream. This has an important bearing on the question of vaccination for cholera. The experimental investigation of vaccination against infective disorders is a product of modern bacteriological research. It is too long a question to deal with in a short article, it is sufficient to say that it is based on the fact that a mild form of the disease may be produced in an animal, which will then be protected from the virulent disease. As in Pasteur's historical experiments, the attenuated or weakened anthrax bacilli were found, when injected into a sheep, to prevent the animal dying when it received a dose of virulent bacilli, which would undoubtedly kill it in ordinary circumstances. This vaccination, when put into practice, was found to diminish the amount of natural anthrax in sheep in France. Similar results have been obtained with the vibrio of Asiatic cholera by some of Koch's assistants, and latterly by M. Haffkine, in the Institut Pasteur in Paris. Haffkine attenuated the virulent vibrio by means of a current of air and other means, and obtained a culture which did not kill animals, but protected them against a subsequent injection of the virulent vibrio itself. The vaccine was also injected into human beings (who lent themselves for experiment), and was found to produce a local inflammation associated with some degree of fever, all the symptoms passing away in a short period. It is probable that the majority of "vaccines" would produce these symptoms. It is, however, a great step to apply vaccination experiments in animals to human beings when the etiology of the particular disease is not completely worked out, and there is, perhaps, too great a tendency in modern research to extend "vaccination" experiments in infective diseases before a correct knowledge of the mode of action of the infective agent has been obtained. It has been pointed out that doubt rests on the vibrio cholerae Asiaticæ as the true cause of Asiatic cholera. It may be; but to impartial observers it has not been proved to be. Vaccination for cholera on a large scale would therefore at present be a mistake, as it might possibly lead to carelessness in the carrying out of better tried preventive measures, which depend not only upon the State but also on the private individual. As a promising field of research, it might be applied to man, since the vaccination itself appears to do no harm. But it requires a long time to decide so difficult a question, and in the meantime the community is face to face with cholera. It is therefore more practical to consider preventive measures than vaccination.

Preventive measures against cholera are of two kinds, those taken by the State to prevent the importation of the disease from cholera-stricken districts, and those which ought to be practised by individuals when cholera is prevalent in the community. Both sets of measures depend upon two well-ascertained facts, viz that each cholera patient acts as a focus of the disease, and that the disease is spread by the evacuations contaminating the water supply. The State can prevent the importation of cholera by quarantine, but this method has been abandoned in England for many good and obvious reasons, and another substituted for it which is considered as likely to be more effectual, but which can only be applied with an efficiently working sanitary organization. In this country we get cholera by ships bringing cholera-stricken people, who are landed. At all the ports, in times of cholera, the ships are boarded by the medical officer, and if any cases of the disease are present they are taken to isolation hospitals, whilst those who are well are allowed to land after leaving their names and destinations. The medical officer of their district is communicated with, and keeps them under surveillance for some days. The cholera ship is moored to a special buoy and disinfected. If no cases of cholera are present on the ship, the passengers and crew are allowed to land, the taking of the names and addresses being left to the discretion of the medical officer who inspects them. It is possible that no better method than this could have been devised, which, with the least inconvenience to the individual, would at the same time keep under surveillance all the imported cases of cholera, and thus check the spread of the disease. It is evident that such a method is quite impracticable without efficient sanitary officers, it would, for example, be useless in a country like Turkey, where the system of quarantine and sanitary cordons exists as in most other European countries. And in our country the application of this method of isolation and surveillance is surrounded by practical difficulties and dangers which may become serious, and which are in any case worthy of discussion. It is quite possible that the medical officer of the port will have too much to do. At present the cholera epidemic at the Continental ports, even in Hamburg, appears to be diminishing, and it may disappear when the cold weather comes, to reappear with unabated virulence next spring. As this is probable, no decrease of vigilance of medical inspection is permissible during the winter months, and it is to be hoped that the sense of security felt by the community at the diminution of cholera on the appearance of cold weather will not extend to the medical officers in whose keeping the general health of the nation lies. If, next spring, cholera becomes disseminated along the Channel on our opposite shore, the medical officers of our ports may be exercised to their utmost in providing accommodation for patients on cholera-stricken ships, and some, apparently well, may proceed to their homes and develop the disease before the medical officer of their district has been advised of their advent. This is, no doubt, a danger which might come even from a ship which has been passed by the port medical officer with a clean bill of health.

The personal measures to be taken when cholera is in our midst are important, but need only be mentioned. Since cholera spreads by the evacuations, these must be disinfected with hydrochloric acid, carbolic acid, or corrosive sublimate as soon as they are passed, and all linen soiled by a cholera patient must be rigidly disinfected. Since the water supply may become contaminated, all water used for drinking, washing utensils, &c., must be boiled, and all articles of food, such as milk, likely to be contaminated with unboiled water, should also be subjected to the heat of boiling water. When these and similar measures for personal protection are rigidly observed, it is not too much to say that cholera will not spread.

## THE PLANET VENUS

M. E. L. TROUVELOT has published a most important and extensive paper on some observations of the planets Venus and Mercury, which for many years past have been occupying his attention. The physical features of the other planets have been treated on previous occasions in like manner, and have extended our knowledge very considerably, so that the reader of this work will be sure to find something really new in the great number of observations that are here recorded. Up to the month of April, 1882, the observations were made at Cambridge, United States, but since then Meudon has been the seat of operations, the air at the latter place did not prove so pure as that in the States, and the horizon not being so open, the number of observations of course was somewhat reduced.

In the work which we have before us the author divides this subject up into nine sections, and we cannot do better than treat of each of them in turn, commencing with the visibility of Venus to the naked eye in full daylight. The best way is, he says, to use the telescope as a pointer, directing it to her by means of the circles, by then looking along the telescope tube he has been able to see her at every point of her orbit, when her angular distance from the sun towards inferior conjunction was not less than  $10^\circ$ , and also towards superior conjunction when she was not less than  $5^\circ$ . Her visibility depended to some extent on the phase she represented, for it is known that the eye can distinguish more easily a disc small and distant than a comparatively larger and nearer crescent. At Cambridge it seems to have been more or less the rule, while at Meudon it was the exception, to see Venus in the daytime, the atmospheric conditions at the latter place being comparatively very bad.

With regard to the general aspect of Venus nothing very striking has been noticed, the part of the limb turned towards the sun, as recorded by other observers, always appeared more brilliant than the more central portions extending towards the terminator. Sometimes the limb was not so bright as usual, being observed to be "dull and without brilliancy," one very noticeable time occurring on April 15, 1878.

Under favourable conditions, whitish and greyish spots can be seen on the surface of Venus, which, at any time, are very difficult to observe. These different-tinted spots give, according to M. Trouvelot, indications of being at different levels. The whitish spots, situated near the terminator, produce on it slight deformations, and seem to so alter it as to suggest that these spots are at a higher level than the other parts. The greyish spots, on the other hand, when situated in about the same positions, also deform the terminator to a small extent, but in an opposite way to those just mentioned, suggesting that these spots lie at a lower level than the parts near them. These two kinds of spots have another peculiarity which has been particularly noticed, and that is their size, the white ones seem to assume a round or slightly oval form, and are nearly always small, but the grey spots are generally of an elongated shape, and are of very large proportions, forming sometimes straight bands. The interval between the appearance and disappearance of these spots is not long, in their formation they are analogous, as M. Trouvelot says, "*avec ces taches diffuses des couches nuageuses continues de notre atmosphère précèdent les pluies, et qu'un simple jeu de lumière fait naître ou disparaître.*" Their contours are always very vague, the whites being a little less brilliant, and the greys a little less dark.

One of the largest spots that has been diligently observed was that which appeared on the 3rd September, 1876. Its size, as will be seen from the figure, was, comparatively speaking, enormous, occupying nearly a third of the illuminated visible surface. At its north and south

extremities it was separated from the terminator by a large white band, the north one being considerably larger than the southern one. Up to the 10th of the same month this spot was still visible, but after that date no trace of it at all could be found. Curiously enough, on February 13th, 1891, another large grey spot (Fig 2), bordered with white, made its appearance, and was very similar to the one we have just mentioned, both with regard to its position and form—indeed, the resemblance was so striking that the spots were considered the same.

FIG. 1.—Showing the large spot on September 3, 1876.

Why it should have disappeared so soon in 1876, and become visible again in 1891, is a mystery which is hard to fathom.

Perhaps one of the most interesting features visible on the surface of Venus are the two snow caps (Figs 3 and 4) at the extremities of her poles. These spots, as M. Trouvelot says, surpass in brilliancy and importance all that he has ever observed. In 1877, on November 13th, a white spot was seen at the north limit of Venus; its brilliancy attracted considerable attention, resembling

FIG. 2.—Large spot visible on February 18, 1891.

very much those situated on Mars. On the following day, another spot, also very striking and of the same character, diametrically opposed, was observed. The question then arose as to the cause of these spots, and we may here quote an entry that was written in the observer's book on the 17th of the same month—"Est-ce que Vénus aurait des taches blanches semblables aux taches polaires de Mars?" The seeing of these spots was by no means a difficult task, and it seemed certain that if

they were snow caps as suggested, perhaps they had been previously observed. This was the case. On June 9 and 17, July 20, August 1 and 27, 1876, and February 5, 1877, observations of these spots had been recorded in the notebook, but owing to their not having attracted very great attention at the time, they were regarded as ordinary spots. That they are analogous to the white spots on Mars is now undoubted: they have the form of a uniform white segment of a circle, which, when seen edgewise, appear as simple lines, they are always exactly 180°

d'aiguilles, qui, parfois, réfléchissent la lumière avec une si grande intensité, que ce bord apparaît tout constellé d'étoiles alignées comme les grains d'un collier de pierres précieuses, sans quelques irrégularités dans cet alignement." The whole appearance seems to suggest that the spots are at a higher level than the contiguous parts of the planet situated at the edge. This idea is also further borne out when the phase of the planet is a small crescent, for then much more of the polar cap is found to be visible than should be the case if the form of the phase

FIG. 3.—The snow caps, February 6, 1877, 10h 45m.

FIG. 5.—Details on the snow caps, January 19, 1878.

apart, sometimes only one is seen because the other is not lighted up by the sun; they are always approximately near the terminator, and seem to oscillate backwards and forwards, balanced, so to speak, around the axis of the planet, and, lastly, they are of a permanent nature, their disappearances being due not to their annihilation, but simply to the fact that they cannot be seen when receiving no light upon them. One main feature in which they differ from the spots on Mars is that they neither increase

was an exact crescent. In many cases a penumbra has distinctly been seen, and in one of them it was so strong and distinct on that part of the terminator lying between the two polar caps, that it lasted for a month, the spots remaining clear and brilliant throughout their entire length. Ever since the year 1700, observers of Venus have remarked these two spots that occupy the polar regions. La Hire and Derham, observing the inequalities of the surface at the extremities of the crescent, believed

FIG. 4.—The snow caps, February 25, 1891, 10h 15m.

FIG. 6.—The snow caps, February 5, 1878.

nor decrease with the seasons, at any rate to a sufficient extent to be sensibly noticed.

When Venus is in a favourable position for observation many details on these spots have been recorded. M. Trouvelot mentions here some bright spots (Figs 5 and 6), which seem to be very numerous, and resemble the bright specks which are seen on the terminator of the moon, "sinon qu'elles sont plus brillantes, surtout sur leur bord interne, et qu'au lieu de petits cratères, elles sont entièrement couvertes et hérissées de pics et

that they could be produced by mountains higher than those on the moon. Bianchini at Rome, Schroeter, Gruithuisen, and several others, all have reported the existence of such markings, but they were never led to conclude that they were snow caps analogous to those on Mars.

To obtain a general idea of the ruggedness and smoothness of the planet's surface, the terminator has helped to considerably distinguish the high and low elevations and depressions respectively. The surface of Venus from

such observations as these has been found to be considerably studded not only with small, but with great differences of configuration, the terminator varying greatly in many phases of the planet. M. Trouvelot's results

FIG. 7.—Showing irregularity of Terminator, November 23, 1877

show that these deformations become most apparent when Venus is at her greatest eastern and western elongations. Sometimes one half of the terminator is seen concave, while at the same time the other is convex

FIG. 8.—Showing indentations at the horns, February 28, 1891

(Fig. 7), small indentations at the horns (Fig. 8) also seem to be of common occurrence, and occasionally the curve of the terminator is perfect, no trace of any irregularity being noticed. Not only then does the terminator

FIG. 9.—February 5, 2h

FIG. 10.—February 5, 5h 43m

change in form, but changes are found to occur very rapidly in intervals of only a few hours. To take one case out of many, we may quote the instance recorded in 1881 on February 5 at 2 p.m. (Figs 9 and 10). At

NO. 1194, VOL. 46]

this time the terminator appeared as a straight line showing Venus then in apparent quadrature, but at 5h 43m this line was quite gibbous, and its curve regular. A very important point about the repetitions of the same deformations is that they do not occur at exactly the same time each day, but appear to change the hour of observation, "the periodicity of these phenomena, if periodicity there is, not being exactly twenty-four hours."

From a long series of observations, the most striking irregularities were found at the extremities of the ter-

FIG. 11.—Showing the shape of the horns, September 27, 1876

minator close to the edge of the pole caps, where deep niches were often recorded. These indentations were noticed to be generally of different sizes and shapes, sometimes the north one being larger than the southern one, and *vice versa*. They also underwent very rapid changes even in the space of a few hours, a case occurring on September 27, 1876 (Fig. 11). "At one time the extremity of one of the horns would be more or less truncated, when the other would be sharp, and some hours later the

FIG. 12.—An abnormal extent of the crescent, May 13, 1881

reverse would be the case, that which was sharp being truncated, and that which was truncated being sharp." M. Trouvelot concludes that his observations bring out a very important fact—"qu'il y a une relation très étroite entre les déformations les plus importantes subies par le terminateur et par les cornes, et les taches polaires de la planète."

When Venus approaches inferior conjunction with the sun, its crescent gradually diminishes until the illuminated surface is turned exactly away from us. Just before this position is reached, the crescent has been found to present

many curious features. The most prominent of them is that this fine crescent is sometimes observed to extend to a greater angular extent than  $180^\circ$  (Fig. 12),  $260^\circ$  of the limb of the planet having once been recorded. Sometimes, by adopting special precautions, the whole circumference has been observed, the obscured disc being completely surrounded by a pale and thin luminous ring. This, as M. Trouvelot says, is of very rare occurrence, for it has happened that although the greatest precautions have been taken, no trace of the planet could be found

FIG. 13.—Showing the bulging out of the crescent as seen on February 24, 1878.

When the crescent is extremely fine, great irregularities have been noticed to mar the continuity of its curve, they differ also not only at different but at the same conjunctions according as the planet is to the east or west of the sun.

Another fact that has been observed relates to the bulging out of the planet (Figs. 13 and 14) at some parts of its visible limb. This was especially noticed in the month of February, 1878, while the crescent was being

FIG. 14.—The crescent as seen on February 26, 1878.

looked at, the south-south east portion seemed to suddenly appear thicker than the remaining part. In fact, the observer in the first instance thought it might have been due to some optical defect in the instrument, but subsequent observation showed that this was not the case, a real change of form having taken place. Two days later this deformation was still more noticeable, the thickness of the visible section being about double what it would have been had it been in its normal condition.

NO. 1194, VOL. 46]

Perhaps one of the most important points referred to in this work is the determination of the period of rotation by means of the spots. This question of rotation is one that has baffled many observers, for the difficulty that has presented itself lies not only in the proper motions of the spots themselves, but in the identification of the same spots after brief periods of time. Glancing over some of the periods already obtained, we find that Schroeter deduced from his observations a rotation of about 24h, basing his value on the movement of a small isolated spot situated in one of the horns. Fritsch's value of 23h 22m, and P. de Vico's 23h 21m 21s, are both also of about the same length. From observations by D. Cassini and F. Bianchini, we have a very wide deviation, the periods of rotation being reckoned in days, the former arriving at a value of 23 days, and the latter at a somewhat larger one of 24 days 8 hours. Coming now to Schiaparelli's value of 225 days, we have here altogether a new departure, the planet rotating on its axis in the same time as it revolves round the sun.

With such values as these it will be at once seen that there is something radically wrong with the spots or their positions on the planet's surface, in some cases, of course, there might have been instances of mistaken identity, but with such an observer as Schiaparelli, who very definitely settles upon a 225 daily period obtained from direct observation, it is hard to conceive that any such sources of error would not have been remarked.

The observations which we have now before us bear out Schroeter's view of a short rotation, Prof. Trouvelot telling us that they were made during the years 1876-78 under exceptionally good conditions. One very interesting point which is of great importance is the fact that these observations were made at the same period, "souvent dans la même journée, sous un ciel également propice et précisément sur la même point de la planète."

The value nearest to 24 hours that Prof. Trouvelot obtained was 23h 49m 28s, and in giving this period he remarks that it is founded on the supposition that the spot had no proper motion. In referring to the period deduced by Schiaparelli he says, "La cause probable de l'erreur de M. Schiaparelli semble résulter de ce fait que les taches  $k$  et  $k'$ , qui ont servi de base à ses conclusions, faisaient partie de la tache polaire méridionale qui, étant située centralement sur l'axe de rotation de la planète, semble rester stationnaire, comme cela se voit sur la tache polaire de Mars, quand elle se trouve réduite à de faibles dimensions." Taking into account many of the general features visible on the planet's surface, such as the rapid deformations of the horns and of the terminator, all these point to short periods of rotation, which, as Prof. Trouvelot points out, is "inconciliable avec la période de rotation, si lente et si inattendue, déduite par l'éminent astronome de Milan."

In concluding our remarks we cannot help mentioning the very complete way in which Prof. Trouvelot has taken into account the prior work in this interesting field of inquiry.

W. J. L.

## NOTES

THE Iron and Steel Institute will meet at Liverpool from Tuesday, September 20, to Friday, the 23rd. Sir Frederick Abel will preside. The following papers will probably be read and discussed:—(Tuesday) on the condensation of ammonia from blast furnaces, by Sir L. Bell, F.R.S.; on alloys of chrome and iron, by R. A. Hadfield; on the Liverpool overhead railway, by J. H. Greathead; (Wednesday) on the engineering laboratories in Liverpool, by Prof. H. S. Ifele Shaw, on the Siemens-Martin process at Witkowitz, Austria, by P. Kapelwieser, on failures in the necks of chilled rolls, by C. A. Winder. (Thursday) on a new process for the elimination of

sulphur, by E. Saniter, on the elimination of sulphur from iron, by J. E. Stead. On Tuesday evening the members and their friends will dine together, and on Wednesday evening there will be a *conversazione* in the Walker Art Galleries, offered by the Mayor of Liverpool and Mrs. James De Bels Adam. A part of each of the first three days will be devoted to the inspection of various works, and on Friday there will be excursions, one party going to Chester, another to Stoke-on-Trent. If a sufficient number of names are given in, there will also be an excursion to the new Water Supply of Liverpool at Lake Vyrnwy.

THE Sanitary Institute, whose Transactions for 1891 are reviewed elsewhere, is holding its thirteenth annual Congress this week at Portsmouth. About 400 members are attending the meetings. The proceedings began on Monday, when Sir Charles Cameron, the president, delivered an address on "The Victorian Era, the Age of Sanitation." He presented a very interesting sketch of the good results which have sprung from the improved sanitary methods of modern times. The frightful mortality of London and other cities in the last century he described as an evil due to insanitary conditions. By the earlier part of the nineteenth century the grosser defects had been remedied, and the death rate had been greatly reduced. For about half a century no further improvement took place, but with the passing of the Public Health Acts of 1872 and 1875 an era of active sanitation ensued, with the result that the death-rate fell sensibly in nearly all the towns. Sir Charles urged that the success of past sanitary work ought to encourage us to redouble our exertions to reduce the urban death rate to at least that of the most healthy of our towns.

THE International Congress of Orientalists finished its scientific labours on Friday last, and every one connected with it agreed that the meetings had been most successful. On Saturday a good many members visited Oxford, while others went to Cambridge. Both parties were cordially received by representatives of the Universities. A meeting held on Monday for the despatch of business brought the proceedings to a close. At this meeting a number of reports and resolutions were read by the secretary, Prof. Rhys Davids. The first resolution proceeded from the Semitic section, and recommended that the Government should be urged to subsidize the study of modern Arabic. The Assyrian and Babylonian sub-section, and also the Egyptian section, passed a resolution in favour of holding at least one combined meeting of the Assyrian and Egyptian sections. The anthropological section expressed its sense of the political as well as the scientific importance of the anthropometric investigations now being conducted in Bengal. The same section also expressed its view of the desirability of forming a collection of Oriental folk lore on a scientific basis. In the Semitic section a committee had been formed, consisting of men of science from different countries, for the purpose of preparing an Arabic Mahomedan encyclopædia. At the head of this committee was Prof. Robertson Smith. The Australasian section desired to express its sense of the immediate necessity of pressing forward research into the physical character, languages, arts, customs, and religion of New Guinea. Count Angelo de Gubernatis moved a resolution, which was seconded and carried, in favour of the establishment of an International Institute of Orientalists, with its headquarters in London. It was decided that the next meeting of the Congress should be held at Geneva in 1894—the meeting to be postponed until the following year if circumstances should render such postponement necessary or desirable. On the motion of Prof. Ascoli, seconded by Prof. Drouil, a vote of thanks to the President was cordially passed. In the evening a dinner was given at the Hôtel Métropole by the Organizing Committee to the foreign members.

THE Perthshire Society of Natural Science is one of the most enterprising of British local societies, and we are glad to hear that it is about to give fresh proof of its energy by extending its museum. This includes two excellent collections—the one a general or index collection, intended, by means of carefully-selected specimens, to act as a guide to the study of natural science, the other, a Perthshire collection, intended to give a complete view of the fauna, flora, and geology of the district. These collections have grown so rapidly that there is not now sufficient accommodation for them. It is proposed that the deficiency shall be met by the erection of a supplementary museum hall and gallery, in which the Perthshire collection will be displayed, while the present building will be devoted chiefly to the index collection.

AN improved spherometer, constructed in Zeiss' optical laboratory at Jena after Prof. Abbe's design, is described in this month's *Zeitschrift für Instrumentenkunde*. It is made to measure down to 0.001 mm. To eliminate errors due to the indefinite nature of the base circumscribed by the three legs of the ordinary spherometer, the surface to be measured is laid upon a circular ring, and the contact rod is screwed up from below. This ring has two sharp concentric edges 0.5 mm. apart, the one for convex and the other for concave surfaces, made of hard steel and ground down to the same level, giving a combination which is less liable to be damaged than a single edge. The ring rests without fastening on a perforated horizontal disc provided with a cylindrical projection which just fits into a hollow in the bottom of the ring. The latter is thus free from strain, and can be easily replaced by another of greater or less diameter. The height of the graduated contact rod is read by a micrometer microscope. The first reading is taken when the contact piece touches a plate of plane polished glass laid over the ring. The plate is then replaced by the surface to be measured, and its radius of curvature calculated by the usual formula.

ON Thursday, the 8th inst., the Cunard Royal Mail twin screw steamer *Campania* was launched from the yard of the Fairfield Engineering and Shipbuilding Company. This is the largest ship afloat, the dimensions being length, 620 feet, breadth, 65 feet 3 inches, and depth, 43 feet. It exceeds the *City of Paris* or *City of New York* by 60 feet in length and 2 feet 3 inches in breadth. The launch of the *Campania* was an ideal one. Although the launching weight of the ship was 9000 tons, there seemed to be not the slightest hitch. At 2.45 p.m. Lady Burns performed the launching ceremony. The huge ship immediately began to move and slowly travelled down the ways, entering the water amidst the loud cheers of some 80,000 people. The Fairfield Company have every reason to be proud of this feat. Not only was the weight to be launched unprecedented, but, the Clyde at this point being very narrow, the big ship had to be stopped immediately she was afloat owing to her great length. The *Campania* will be driven by two sets of triple expansion engines, each set having five cylinders arranged to drive a three-throw crank shaft, the cranks being set at the angle of 120 degrees from each other, there are two high-pressure cylinders, one intermediate, and two low pressure cylinders, the high-pressure being placed above the low-pressure cylinders. These engines together will indicate about 25,000 horse-power. Steam will be generated by twelve large double ended boilers with ninety-six furnaces. An auxiliary single-ended boiler is used for supplying the steam for the electric lighting and secondary purposes throughout the ship. The main boilers are arranged in two groups, each group having a funnel 19 feet in diameter. It is expected that the speed attained will reach twenty-two knots on the trial, and it is hoped, when the engines have settled down to their work, that this speed may be attained on the Atlantic.

THE weather has remained very unsettled during the past week, owing to the complex distribution of barometric pressure, there being during the first part of the time low pressure areas over the northern parts of the kingdom, while an anticyclone lay over France and the Bay of Biscay. These conditions caused a considerable amount of rain, especially in the north and west, although in the southern and eastern parts of the country, the weather was fair, with mist or fog in places. During this period the maximum temperatures rarely exceeded 65° in any part, on Sunday and Monday, however, the anticyclone moved eastwards, and gave place to large depressions from the westwards, rain being general, except in the south-east of England, where the maximum temperatures rose to 70° and upwards, and similarly high readings occurred in the midland and southern districts. On Tuesday a cyclonic disturbance was crossing Scotland, and heavy rain was reported there and in the north-west of Ireland. The Weather Report for the week ending the 10th instant shows that the mean temperature was below the average over the whole of the United Kingdom, and although fairly high day temperatures were registered, the night readings were below 40° generally, and in the east of Scotland they fell to within a degree of the freezing point. The rainfall for the same period was generally less than the normal, and in the south-west of England there was still a deficiency of 8 inches since the beginning of the year.

IN his report on the rain, river, and evaporation observations, made in New South Wales during 1890, Mr. Russell states that the widespread interest in rainfall records is rapidly adding to the number of observers, which now amounts to 1088. The year was conspicuous for abundant rainfall, causing heavy floods in the river Darling, far exceeding those of which there are complete accounts. The average rainfall for the whole colony was 32.73 inches, being 32.6 per cent. greater than the average for the previous sixteen years. The report contains the results of interesting experiments on the effect of forests and elevation on the amount of the fall. At Dinby, which is situated in a densely timbered country, the amount was 35.89 inches, while the mean of nine of the nearest stations gave 38.92 inches. As an instance of the effect of elevation, the average rainfall at Wallongong, half a mile from the sea, at an elevation of 67 feet, is 38.84 inches, while at Cordeaux River, six miles from the sea, it is 55.53 inches.

THE Annual Report of the Acting British Resident of Perak for the year 1891 contains monthly summaries of meteorological observations at nine stations, and a chart showing the comparative range of monthly rainfall during the years 1888-91 at Taiping. The highest recorded temperature in the shade was 97° at Kuala Kangsar and Parit Buntar in the months of March and April respectively, the lowest 62°, in February, at Taiping and Salama. The only solar thermometer, that in Taiping, registered 121° in March and May. The rainfall varied from 85.6 inches at Teluk Anson to 183 inches at Topah. It is well distributed throughout the year, the driest months being May to July.

A MOST unusual phenomenon was seen in the Maltese Islands on July 21, when a thunderstorm raged for twelve hours, and deposited three inches of rain. According to the *Mediterranean Naturalist*, it is fifty-five years since rain fell in Malta in the month of July.

IN the annual report of the British Museum (Natural History) reference is made to two "principal events" relating to the conservation and arrangement of the Zoological collections. The first is the enlargement of the building which contains the collections of specimens preserved in spirits. An enlargement had been rendered necessary mainly by the reception of the *Challenger* collections, which proved to be more extensive

than had been anticipated. The addition to the building is already roofed in, and may be ready for occupation within the next twelve months. The other matter of exceptional importance is the arrangement of the collection of birds' eggs. In the old Museum this collection consisted of a small number of specimens of more or less great historical value, and of an imperfect series of deteriorated specimens of the British species, which were exhibited in three table cases. The first important addition was received in the "Gould" collections, purchased in 1881; other miscellaneous series followed, and, finally, the magnificent donations of European Asiatic species by Messrs. Goldman, Salvin, and Seebohm, and of Indian eggs by Mr. A. O. Hume, added so much to the number of specimens, and imparted such a great value to this collection, that its systematic arrangement could be no longer delayed. At the same time the formation of a perfect series of British birds' eggs for exhibition and consultation by the public had become more and more urgent. A requisite grant having been made by the Lords Commissioners of the Treasury, Mr. Seebohm undertook the work of arranging both the general and the British series, and in the course of this year he has made such progress that about 24,000 specimens, belonging to fifteen families, are catalogued and beautifully arranged in thirteen cabinets, and that the British series can probably be opened to the public in the present year.

THE authorities of the French laboratory of physiological psychology have sent a circular to painters, sculptors, and designers, asking them to answer various questions as to their visual memory of colours and forms. Some replies have already been received, and one of the things noted in several of them is that the writers are able, when they see a painting, to perceive at a glance whether the artist has a good visual memory or not.

MR. M. A. DUMONT contributes to the current number of the *Revue Scientifique* an interesting paper on the history of the population in a small rural commune, Saint-Germain des Vaux. He has closely examined the communal registers from the early part of the eighteenth century until the present day. It is curious to see how the tendencies not only of the commune, but of its individual families, with regard to the increase or decrease of population, correspond to those of the French nation as a whole.

THE *New Bulletin* for September opens with a section on Caraguata fibres. Samples of the Caraguata plant were obtained through the Foreign Office from Dr. Stewart, British Consul at Asuncion, and submitted to Mr. J. G. Baker, by whom the plant is here described. The number also contains Decas III of "Decades Kewenses," "New Orchids: Decade 3," and sections on Lagos palm oil and some vanillas of commerce.

WE learn from the *Kew Bulletin* that a handbook of Australian fungi has been prepared by Dr. M. C. Cooke, Mycologist in the Herbarium of the Royal Gardens, Kew, and published under the authority of the several Governments of the Australian Colonies. It contains a full description of all the fungi so far known to occur in Australia and Tasmania, number 2084 species. All the genera are illustrated by 36 plates, 20 of which are coloured.

MR. VICE-CONSUL SCRATCHLEY, of Philippeville, Algeria, has presented to the Museum of the Royal Gardens, Kew, an axe, scraper, and knife, such as are used in the collection of cork in Algeria. The *Kew Bulletin* says that the Museum contains numerous illustrations of the applications of cork, the bark of the cork oak (*Quercus Suber*, L.). The tree grows in Spain, Italy, South of France, and Algeria, and this first crop of cork is taken from the trunk as it stands, at the age of about thirty

years, and afterwards at intervals of from six to ten years. The later crops furnish the best bark, which is used for bottle corks and similar purposes.

IN his annual report to the Secretary of the Science and Art Department, Dr. V. Ball, Director of the Science and Art Museum, Dublin, says that throughout the past year Major McEniry was continuously engaged in the rearrangement of the Royal Irish Academy collections. Mr. W. F. Wakeman rendered valuable assistance in preparing descriptive lists of the "Crannog finds," and Mr. George Coffey made a catalogue of the Irish coins. Both have been printed, and will serve as valuable records, for future reference, of the present condition and contents of these two branches of the collection. They will, moreover, afford useful material in the preparation of a contemplated handbook to the collection, which now claims attention, but for which some special arrangement will have to be made. In the same report Dr. Ball notes that under the efficient management of Mr. Moore the Royal Botanic Gardens, Glasnevin, maintained during the year their now well-established position as one of the principal centres of scientific horticulture in the United Kingdom. The continued and widespread interest in the operations carried on there is amply shown by the generous support which plant growers still afford by their contributions of novelties.

MR. E. S. MORSE, Director of the Peabody Academy of Science, has been investigating the older forms of terra-cotta roofing tiles, and presents the results of his inquiry in the latest Bulletin of the Essex Institute, Salem. His paper is a valuable contribution to the study of a very interesting subject. The earliest known form of tile consists of two elements—a wide tile (tegula) either square or rectangular, more or less curved in section, and a narrow semi-cylindrical tile (imbrex), usually slightly tapering at one end to fit into the wider opening of the one adjoining. The tegula is placed on the roof, concave face upwards, and the imbrex, placed concave face downwards, covers the lateral joint between two adjacent tegulae. Tiles of this kind covered the roof of the very ancient temple of Hera at Olympia, the form being identical with that of tiles still used in the remote East. Afterwards the form was modified in Greece and Italy. In one or other of its varieties, this tile—which has been called by Graeber the normal tile—is found all over Asia, in Asia Minor, and in the countries bordering the Mediterranean. The well-known pantile combines the two elements, imbrex and tegula, in one piece. It originated in Belgium or Holland, and is used mainly in those countries, in Scandinavia, and to some extent in England. The flat tile is simply a shingle in terra-cotta, and has no genetic relation to the other forms of tiles. It is used in Germany, Austria, Poland, Switzerland, France, and England. Mr. Morse's paper is well illustrated, and contains a map showing the geographical distribution of these three types of tile.

MR. WALTER HOUGH contributes to the report of the U. S. National Museum for 1890, just issued, a very good paper on the methods of fire-making. Having in a previous paper discussed the apparatus of fire-making, he now deals with the handling of the apparatus. All mechanical methods of generating fire take advantage of the law that motion, apparently destroyed by friction, is converted into heat. These methods can be grouped under three classes—(1) wood friction, (2) percussion of minerals, (3) compression of air. Three other methods exhaust the entire range of usages in fire-making, and, with one exception, they are perhaps recent. These may be arranged in the following classes—(4) chemical, (5) optical, (6) electrical. These exhibit the action of friction in its highest manifestations. Each method Mr. Hough examines in

turn. His exposition is concise and clear, and carefully illustrated.

SEVERAL sponge deposits have been discovered at a distance of about 150 metres from the western shore of the island of Pantelleria (depth about thirty metres). Five Greek vessels, with two divers, obtained in three days about twenty-five quintals of sponges of the finest quality.

Two papers which will be included in the forthcoming Macleay Memorial Volume were read at the meeting of the Linnean Society of New South Wales on July 27. One of them, by Prof. F. W. Hutton, is on the Pliocene Mollusca of New Zealand. It gives a complete list of the Mollusca hitherto met with in the Pliocene fossiliferous beds of New Zealand. Such beds have been found only in the southern and eastern parts of the North Island. About 64 per cent of the Pliocene Mollusca are also found in Miocene rocks, but the Pliocene fauna is well characterized firstly by the presence of the genera *Trophon*, *Columbella*, *Lurricula*, and *Mytilicarda*, by the absence of certain genera present in Miocene strata, and thirdly by the small size of sundry species common to both formations. From the recent fauna, that of the Pliocene is distinguished by the presence of from 23–37 per cent of extinct species, and of a number of genera no representatives of which up to the present time are known to inhabit New Zealand seas. The Pliocene fauna, therefore, seems to be the remains of an earlier fauna disappearing rapidly before the conquering host of the recent fauna, which had invaded New Zealand some time previously. The other paper is by Prof. W. Baldwin Spencer, and offers contributions to our knowledge of *Ceratodus*, with special reference to the blood vessels.

AT the same meeting of the Linnean Society of New South Wales, Mr. Rainbow exhibited the two sexes of an undescribed Sydney spider (*Nephila* sp.), the webs of which were said to be strong enough to catch male birds.

MR. A. C. GATTO writes in the *Mediterranean Naturalist* that the pretty moth *Deiopeia pulchella*, Bois, has occurred this year in Malta in unusual abundance. On August 10, when his note was written, and for a fortnight before, it was the commonest moth to be seen on the wing in the island. He does not remember ever to have had occasion to record such extraordinary numbers of any butterfly or moth. This remarkable abundance he supposes to be due to the fact that the rains of the late spring caused an overgrowth of the *Heliotropium europaeum*, on which the *Deiopeia* feeds. The moth is white, with small red and black spots on the forewings, and with white underwings bordered with black. It is subject to much variation, sometimes the black dottings predominating, sometimes the red ones, but it is a very characteristic form and easily distinguished.

A NEW edition of Mr. Alfred Gibson's well-known "Agricultural Chemistry" has been issued by Messrs. Routledge and Sons. The book was originally issued more than thirty years ago, and there has been a steady demand for it ever since. In preparing the present edition the author has had the help of his nephew, Mr. A. E. Gibson, in making such changes as the advance of agricultural chemistry has rendered necessary.

MESSRS. MACMILLAN AND CO. have issued a new edition of Mr. W. H. H. Hudson's "Arithmetic for Schools." The work has been enlarged and very carefully revised.

THE University College of North Wales, Bangor, has issued the prospectus of the work to be done by its agricultural department during the session 1892–93. The fund for the promotion of agricultural education amounted, in the session 1891–92, to £1900, and was derived partly from a grant by the Board of

Agriculture, partly from private subscriptions, and partly from grants by the County Councils of Anglesey, Carnarvonshire, and Montgomeryshire. A considerable sum was also contributed locally to meet the expenses of field experiments, dairy demonstrations, and Extension lectures. Two things are aimed at in connection with the College scheme of agricultural education — (1) To provide at the College as complete a training in agriculture and the sciences related to agriculture as can be obtained at any of the recognized Agricultural Colleges, and especially to provide such a training as would be suitable for land agents, farmers, bailiffs, and young men who intend emigrating with a view to farming in one of the colonies. (2) To make the College a centre of agricultural education for North Wales, and to organize in the six northern counties of the Principality, in connection with the College, a system of instruction to meet the special wants of each agricultural district, and supply a graduated system whereby pupils may pass from the School to the College. Several local landowners and farmers have enabled the College to make arrangements by which farms in the neighbourhood of Bangor can be used by the lecturer in agriculture and the members of his classes for the purpose of practical instruction.

In a paper on the Ainos of Yezo, contributed to the latest report of the U.S. National Museum, Mr. Rymyn Hitchcock refers to the arrow poisons used by the Ainos. The method of preparing these poisons has been revealed to only one traveller, Dr. B. Scheube, who believes his information to be correct, as the accounts obtained from different localities entirely agree. His account is as follows:—The young side roots of *Aconitum Japonicum* are usually gathered in summer and dried in the shade until autumn. The roots which contain active poison become softer, while the others grow harder, apparently a process of fermentation takes place. The former, after the removal of the skin, are rubbed between two stones to a pasty mass. There is no further preparation. This material is either spread directly upon the arrowheads or preserved. The poison maintains its activity for five months. Dr. Scheube adds that in every village the poison is prepared only by a few old men, not because the process of preparation is unknown to the others, but because these men have had experience in its production. Prayers, magic formulas, and the like are not recited during the preparation. The activity of the poison is tested by a portion being placed on the tongue. To ensure its action each arrow receives portions from three different preparations. Dr. Stuart Eldridge has made some chemical and physiological investigations of this poison, which confirm the supposition that aconite is its active ingredient. But Dr. Eldridge declares that the pulp prepared as described is mixed with other ingredients, which he has been unable to identify, but which are probably inert, and the resulting mass is buried for a time in the earth. On removal from the earth the poison, he says, appears as a stiff, dark, reddish brown paste, through which fragments of woody fibre are distributed, and the poison, when applied to the arrow, is mixed with a certain proportion of animal fat. Mr. Hitchcock secured two specimens of the poison, which are in the form of hard lumps. Specimens of the plant from which the poison is obtained were collected by Mr. T. Holm, and determined by him as *Aconitum Japonicum*. In some parts of the country it grows in great abundance, and the fine purple flowers are very pleasant to the eye.

In their very interesting account of various plants growing in and through the shells of marine mollusca (noticed by us in NATURE) Bornet and Flahault called attention to some fungoid-like hyphæ, which were recorded under the names of Ostracoblabe and Lithophyllum, but in the absence of any fructification or of very definite characters, their position was not more accurately determined. Dr. Bornet, on looking over the fourth part

of the *Berichte der deutschen botanischen Gesellschaft* was struck by the resemblance of *Lithophyllum gangliiforme*, B and F, to the deeper hyphæ of *Verrucaria calicada* as represented by M. Bachmann in figures 3 and 4 of plate 1x accompanying his memoir (*Die Beziehung der Kalkflechten zu ihre Substrat*) and it occurred to him that the hyphæ found perforating the marine shells might be those of lichens. To verify such an idea, Dr. Bornet spent some time at Croisic towards the close of the summer of 1891. Here, of the shells gathered at low-water mark or not uncovered at each tide, a large number had the calcareous portions traversed by filaments of *O. implexa*. Sometimes these filaments were solitary, at other times and more frequently they were accompanied by one or more of the perforating Algæ (*Gomontia*, *Ostreobium*, *Mastigocoleus*, *Hyella*), but nothing either in or externally seemed to indicate that they were the hyphæ of a Lichen. When the shells were gathered off the rocks at a height at which they were frequently out of the water, a large number were found to present discoloured patches covered with dark depressed spots formed by the spermatogonia and apothecia of a *Verrucaria*. The shells of *Purpura lapillus* with the mollusc, or serving as a home for some hermit crab, were the more frequently attacked. Some shells of *Patella* and *Balanus* were also attacked. When thin sections were made, perpendicular to the surface of the shell, the outer border appeared granular and was nearly opaque, the hyphæ and the alga condensed in the gonidial layer, having caused the semicrystalline shell structure to disappear, leaving it in a powdery state. But deeper in that portion of the shell which in part preserved its transparency the filaments could be seen perforating it to a considerable extent, and these presented all the characters of those described by Bornet and Flahault as belonging to *O. implexa*, with the sole exception that the fusiform dilatations were not observed. On decalcification the gonidia were found to be mostly supplied by *Mastigocoleus testarum*, some few by *Hyella caespitosa*. Towards the margin they were reduced to the condition of isolated cells, but deeper down, the long branches of the thallus were found little altered and most easily recognisable, presenting a most favourable example of the connection existing between the gonidial stages of the filamentous alga. M. l'Abbé Hue recognized the lichen of *Purpura lapillus* as *Verrucaria consequens* (Nyl). It will be noted that the hyphæ of this *Verrucaria* are capable of living isolated, not except under certain conditions uniting with the algal forms, these latter requiring the presence of the open air from time to time, so that the lichen stage is not developed on the shells always submerged. *Lithophyllum gangliiforme*, though carefully looked for, was not met with, but its history, when known, will no doubt be equally interesting.

DR. A. B. GRIFFITHS writes to us to explain, in answer to a criticism which appeared in the recent review of his book, "The Physiology of the Invertebrata," that it is extremely difficult to determine in what state of combination uric acid exists in the urine of invertebrates. He, however, considers it more than probable that both potassium and lithium occur in the urine of some of these animals.

THE additions to the Zoological Society's Gardens during the past week include two Philantomba Antelopes (*Cephalophus maxwelli*) from Sierra Leone, presented by Mr. P. Lemberg, two yellow-bellied Liothrux (*Liothrux luteus*) from China, presented by Mr. J. Holmes; four Poe Honey Eaters (*Prothemia-dera nova-zealandia*) from New Zealand, presented by Capt. Edgar J. Evans, R.M.S. *Taiwan*, a Little Grebe (*Tachybaptus fluviatilis*), British, presented by Mr. Thomas Riley, a Hoopoe (*Upupa epops*), a Greater-spotted Woodpecker (*Dendrocopos major*), twelve Fire-bellied Toads (*Bombinator igneus*), European, purchased

## OUR ASTRONOMICAL COLUMN

**DISCOVERY OF A NEW SATELLITE TO JUPITER**—A telegram from New York announces that Prof. Barnard, of the Lick Observatory, Mount Hamilton, California, has discovered a fifth satellite to Jupiter. It is of the thirteenth magnitude, with a period of revolution round the primary of 17h 36m, its distance from the centre of the planet being 112,400 miles.

**VARIATION OF LATITUDE**—Dr. Chandler, in the *Astronomical Journal* No. 273, concludes his series of very important articles on the discussion of observations with regard to the cause of the variation of latitude. The material he has used comprises more than thirty-three thousand observations, made in seventeen observatories with twenty-one different instruments, as many as nine distinct methods of observation having been employed. Out of the forty-five series in which these observations are arranged, only three show results which do not harmonize with the general law as stated in the fifth article (see "Astronomical Notes," *NATURE*, vol. xlv, p. 211). The values of the three come out negative, and as they are numerically small, they can be with justice discarded, for, as Dr. Chandler says, "a mere rejection of a single discordant equation (out of a total number of 427), in two cases, and of two in the third, would convert them into positive values." Instead, then, of the ratio of the difference of the two moments of inertia to the principal one being  $1^{\circ} 18'$ , and perfectly uniform as given by theory, observation suggests the value of  $85'$  (for 1875), the motion not being uniform but subject to a slow retardation which "in its turn is not uniform." The first difference was soon found by Prof. Newcomb to be due to a defect in the theory, an allowance of the earth's elasticity not having been taken sufficiently into account, but with regard to the second he urges an objection "on the ground of dynamic impossibility." In such a discussion as this of course an outside opinion cannot be counted of much value, but we quite agree with Dr. Chandler that if an observed fact disagrees with the result of theory, and a flaw is found in the theory, there can be no reason why another observed fact of equal weight, but also in discord with theory, should be regarded as "impossible."

**BRIGHT STREAKS ON THE FULL MOON**—In *Astronomische Nachrichten*, No. 3111, Prof. Pickering gives a brief condensed account of the investigation that has been carried out at Arequipa with regard to the systems of bright streaks, especially round prominent craters, that are visible on our satellite at the period of the second and third quarters. The instrument employed was the 13-inch, and the magnification ranged from 450 to 1120 diameters. The chief results noted were—(1) That the streaks of the systems round many of the large craters are not oriented to the centre of the prime crater, but towards other craters whose dimensions are considerably smaller. (2) These minute craters are extremely brilliant, and rarely exceed one mile in diameter. (3) Some streaks are found to lie across or upon ridges, these are very seldom connected with small craters. (4) In the case of Copernicus, streaks are found to start from craterlets inside the rim and low up the inner side of the walls, and down the other side. The rim of Tycho also contains similar craterlets, but the streaks do not extend very far. (5) A difference in colour was noticed between the streaks systems of Copernicus, Kepler, and Aristarchus, and those of Tycho, the last-mentioned being considered whiter than the others. (6) There are no very long streaks, their general length may be reckoned from ten to fifty miles. What have been previously taken for long streaks are found, by minute observation, to be simply a series of these smaller ones connecting up, apparently, many small craters. That extending from the regions of Tycho across the Mare Serenitatis is so constructed. In seeking an explanation to account for the origin of these bright streaks, Prof. Pickering suggests that if, for example, the craterlets on the rim of Tycho were constantly emitting large quantities of gas or steam, which in other regions was being absorbed, "we should have a wind uniformly blowing away from that summit in all directions." Should other craterlets in the vicinity "give out gases mixed with any fine white powder, such as pumice, this powder would be carried away from Tycho, forming streaks." This hypothesis, besides explaining the presence of the streaks themselves, satisfies very well the fact that they can only be seen after and before the first and last quarter of the moon phase, for it is only at this time that the contrast would be best seen.

**NOVA AURIGÆ**—On the receipt of Mr. H. Corder's information relative to the brightening of Nova Aurigæ, Mr. Espin made an examination of its light on August 21, and found that the star was of the 9.2 magnitude. Since then Prof. Kustner has also observed it (August 31, 11m 4 Bonn mean time), and reckoned it to be as bright as on March 21 last. The Astronomer Royal's photographic determination, made on August 30, accounts it to be about the 12th magnitude.

**NEW OBSERVATORIES**—Mount Monnier, in the Maritime Alps, has been visited by M. Bischoffsheim and M. Perrotin, with the object of setting up a new observatory. It is proposed to raise on the summit (2800 metres altitude) an observatory, the work of which will be commenced next April. *L'Astronomie* for September also informs us that the Astronomical Observatory of Abbas Touman (lat. N  $41^{\circ} 46'$ , long. E. Paris,  $40^{\circ} 32'$ ) will be ready for work in a few weeks. The observatory is already installed with a refractor of 29 inches, and as it is situated at a considerable height, it will be used for those special stellar studies which are difficult at Pulkowa, Moscow, and Kazan.

**SOLAR OBSERVATIONS AT ROME**—Prof. Tacchini, in the July number of *Memorie della Società degli Spettroscopisti Italiani*, gives in tabulated form the results of the observations made at the Royal College with reference to the prominences seen at the sun's limb during the months of April, May, and June. In the table showing the frequency of these phenomena for every 10° of latitude north and south, we find that the numbers for the three months respectively were 83, 97, and 147 for the north, and 75, 110, and 183 for the south latitudes. This shows an excess of 41 for the south, the zone in which they mostly occurred being ( $-50^{\circ}$  to  $-60^{\circ}$ ) the zone of greatest frequency for the north was ( $+60^{\circ}$  to  $+70^{\circ}$ ). The frequency at the equator was comparatively small, 26 and 23 being the numbers recorded for the zone of 10° each side.

## GEOGRAPHICAL NOTES

A REUTER telegram from St. John's, dated September 11, says that the steamer *Kite*, which left that port three months ago to relieve the Peary Expedition, has just arrived there, after having successfully accomplished its object. Lieutenant Peary, who is an engineer in the United States Navy, left America early last year in command of a small expedition consisting of only five men, the object of which was to spend one or more winters in Greenland for the purpose of scientific observation, and to make an attempt to reach the North Pole across the interior of Greenland. The commander of the expedition was accompanied in this arduous enterprise by his young wife. The winter quarters of the party were fixed at McCormick Bay, whence Lieutenant Peary travelled 1300 miles northwards over the inland ice, which he found to be in a favourable condition for his journey. After making some important discoveries, the explorer returned to the quarters at McCormick's Bay, where, according to previous arrangements, he awaited the arrival of the relief expedition. Lieutenant Peary, his wife, and his five men are all well. Lieutenant Peary's great sledge journey commenced on May 15 last on the true ice cap of Greenland at the head of McCormick's Bay, and at an elevation of four thousand feet. The explorer, who took with him only one man and fourteen dogs to draw the sledge, passed along the edge of the Humboldt Glacier and then across the feeder basins of the St. George's and Osborne Glacier system. On June 26 he reached the 82nd parallel. Here the coast trended to the north-east, and then east, and finally compelled the explorer to pursue a south easterly course. After four days' march, during which the coast still stretched south-east and east, Lieutenant Peary reached the head of a great bay in latitude  $81^{\circ} 37'$ , and longitude  $34^{\circ}$ . This was on July 4, and in honour of the day he named this opening Independence Bay. The glacier terminating on its shores he called the Academy Glacier. The land here was of a red-brown colour and free from snow, and flowers, insects, and musk oxen were abundant; while horses, foxes, and ptarmigan were also seen. On July 9 Lieutenant Peary and his companion started on their return journey, taking a more inland course, and in seven days' time they were travelling over soft snow on the interior plateau, at an elevation of 8000 feet.

The explorer then again descended to the coast, covering thirty miles a day. He met the *Kite*, with the relief party, on August 4, near the head of McCormick's Bay, having completed his original programme to the very letter. The geographical discoveries made by the expedition include the tracing of the Greenland coasts above the 79th parallel, the termination of the continental ice-cap below Victoria Inlet, and the existence of glaciers on all the northern fiords. Many valuable tidal and meteorological observations were also obtained, as well as a quantity of material for the ethnological study of the northern Eskimo, including specimens of their costumes, tents, and sledges. The expedition brings home, besides a number of photographs of natives and of Arctic scenery, a large collection of the flora and fauna of the high latitudes visited.

THE four Dundee whaling vessels, whose intended voyage to the Antarctic seas has been already referred to in these notes, sailed from Dundee last week. Three of the vessels carry surgeons who have been specially instructed in making meteorological and biological observations. They are fully equipped with appliances for collecting specimens of every kind. The more strictly geographical conditions will be observed by the captains, who have been supplied with additional instruments to enable them to lay down their track with a greater degree of accuracy than would be necessary in ordinary circumstances. Their long Arctic experience fits them for navigating the ice hampered waters of the South and for comparing the conditions found there with those of the better-known North Polar zone.

THE railway from Jaffa to Jerusalem is now practically completed, and will be opened for traffic before the end of this month. Recent events in Russia have caused a great increase in the Jewish population of Jerusalem, leading to the extension of the city beyond the walls. The railway will do much to promote the prosperity of Palestine and will probably be largely utilized.

THE Gilbert Islands, in the Central Pacific, have been definitely brought under British protection. The group is bisected by the equator, and forms the central link in the long chain of coral and volcanic islands which stretches from the northern to the southern tropic between the meridians of 160° and 180° E. The Marshall Islands, which are the most northerly of this chain, are under German control.

THE Proceedings of the Royal Geographical Society for September publishes an interesting account of a journey in Sikkim undertaken by Mr C. White and Mr Hoffman in July 1891, with the purpose of exploring and photographing the surroundings of Kanchenjunga. The travellers crossed by the Zeumtso La pass into the Tremu Valley, the magnificent glacier in which was visited for the first time by Europeans. The main glacier—fifteen miles long—is joined by the union of six smaller glaciers, and several others were observed which could not be approached. The Tremu Valley was proved to be only a fortnight's journey from Darjiling, a fact which makes the almost entire ignorance of the existence of glaciers in it very remarkable.

IN the course of his travels into the interior of Iceland (*Petermann's Mittheilungen*, vol. 38), Th. Thoroddsen discovered an unknown lake in the unexplored region of Vatnajökull. "The greatest part of the western edge of the Vatnajökull is formed by a mighty glacier, whose margin stretches with faint curvature towards the southern horizon. The mountain chains which reach the glacier are powerless to influence its shape. We were surprised by the discovery of a very long lake, stretching from the margin of the glacier close to us towards the south-west as far as the eye could see, and filling up the valley between us and a parallel mountain chain. The narrow lake is of a milk-white colour, formed as it is by glacier ice. I named it Langisjor. The glacier reaches with its steep flank to the north end of the lake, and as it is riddled with clefts it is impossible to ride round on this side. The landscape round the lake is of magnificent beauty, only vegetation is quite absent. The greenish-white lake is surrounded by red and yellow tuff hills, with innumerable fantastic points and summits. On the other side of the chain which terminates the lake in the south stretches an extensive flat plateau, in which glitters a large watercourse, probably the Skapta, and far to the south are seen some great lava streams, dating probably from the 1783 eruption."

# INTERNATIONAL CONGRESS OF PHYSIOLOGISTS

THE second International Congress of Physiologists, which took place at Liège on August 29, 30, and 31, was attended by more than 100 physiologists, including among others—Prof. F. Holmgren (Upsala), President of the Congress, Profs. Hansen, Hürthle, Kühne, Rosenthal, Cybulski, Kronecker, Miescher, Fredericq, Heger, Heymans, Arloing, Chauveau, Dastre, Gréhaud, Hédou, Langlois, Lavalan, Morat, Wertheimer, Hamburger, Grigorescu, Wedensky, and the following English members: Profs. Foster, Burdon Sanderson, Schafer, Allen, Gotch, Halliburton, Horsley, Purser, Waymouth Reid, Stirling, Waller, Drs. Adams, Beevor, Paton, Martin, Mott, Pye-Smith, Sherrington, Starling, Shore, Sims Woodhead, Messrs. Bayliss, Burch, and Parsons.

The work of the Congress was carried on in the Institutes of Zoology and Physiology, these institutions being placed at the disposal of the members by the kind courtesy of the two directing professors, whilst in addition the whole arrangements were excellently organized through the energy of the Professor of Physiology, Prof. Léon Fredericq.

The work of each day was so arranged that the mornings only need be devoted to the formal hearing of communications in the large lecture hall of the Zoological Institute, and the afternoons were thus left entirely free for informal meetings in the Physiological Institute, when demonstrations of special interest were shown in the rooms of the laboratory, thus adding very materially to the interest and utility of the proceedings. The following list of the various communications and demonstrations will at least serve to show the large extent of ground covered by the subject-matter brought forward, and the activity with which physiological research is now being pursued.

MONDAY, AUGUST 29.—PRESIDENTS: PROF. CHAUCHEAU (Paris), PROF. BURDON SANDERSON (Oxford).

## A. Communications

1. Hermann—Phonophotography
2. Rosenthal—Results of observations with improved calorimetric methods
3. Halliburton—Nucleo albumins
4. Starling—The fate of peptones in the blood and the lymph
5. Max Cremer—Experiments on the effects of feeding animals with certain sugars
6. Langlois—The functions of the suprarenal bodies
7. Morat—The innervation of the tensor tympani
8. Hamburger—The effect of different salts upon the properties of red blood corpuscles
9. Celine Muro—Physiological evolution

## B. Demonstrations

1. Hürthle—A new method of registering the sounds of the heart in man by means of a microphone
2. Wertheimer—(a) The excretion by the liver of bile introduced into the blood  
(b) Vaso-dilatation effects of strychnia
3. Lavalan—The cardiograph (needle method)
4. Wedensky—Demonstration by the telephone of the electrical changes which accompany the passage of nerve impulses, and the influence upon these of electrotonic alterations in nerve excitability
5. Sherrington—The cortical representation of the movements of the hallux and especially of the anus in the Macaque monkey
6. Langlois—The variations in the discharge of heat during "la maladie pyocyaneque."

TUESDAY, AUGUST 30.—PRESIDENTS: PROF. KÜHNE (Heidelberg), PROF. HÄGER (Brussels).

## A. Communications

1. Bowditch—Composite photography
2. Olivier—Protoplasmic continuity
3. Schafer—The structure of the insect's wing muscles
4. Schafer—The negative effects of severance of the frontal lobes of the cerebrum
5. Vitzou—(a) The visual centres of the dog and monkey  
(b) The effects of total ablation of a cerebral hemisphere.

- 6 Wertheimer —The elimination of pigments by the liver
- 7 Loew —The distinction between the "active" and the "passive" albuminous material of plants
- 8 Sherrington —The varieties of leucocytes.

#### B Demonstrations

- 1 Chauveau —The changes in mammalian endocardiac pressure as recorded by the tambour and air transmission method (This classical experiment formed the main part of the afternoon's work)
- 2 Gréhan —(a) Absorption of carbonic oxide by living organisms
- 3 Gréhan and Martin —On the physiological effects of opium
- 4 Wedensky —Demonstrations with the telephone upon nerve excitation and upon voluntary muscular contraction in man
- 5 Zwaardemaker —The mechanism of smell

WEDNESDAY, AUGUST 31 —PRESIDENTS PROF WEDENSKY (St Petersburg), PROF GRIGORESCU (Bucharest)

#### A Communications

- 1 Cybulski —The use of the condenser for the excitation of muscles and of nerves
- 2 Hédon —The effect of removal and of transplantation of the pancreas upon the production of diabetes mellitus
- 3 Gotch —The increased excitability of nerve and of muscle occasioned by low temperature
- 4 Burch —(a) The apparatus for photographing the movements of the capillary electrometer  
(b) The method of analyzing the electrometer curves obtained by the photographic method
- 5 Burdon Sanderson —The electrical changes in muscle as shown by the capillary electrometer
- 6 Fredericq —Autotomy in crabs.
- 7 Jacobi —The muscular sense
- 8 Bayliss —The functions of the depressor nerve
- 9 Doyon —Tetanus
- 10 Wedensky —The impossibility of causing fatigue in motor nerves.
- 11 Verworn —The effect of galvanic currents on simple living organisms
- 12 Moussu —The functions of the thyroid body
- 13 Slosse —(a) The functions of the thyroid body,  
(b) Autopsy of a case of thyroidectomy in the dog
- 14 Kaufman —The intra-muscular circulation
- 15 De Boeck —The effects of partial ablation of the cerebrum immediately after birth

#### B Demonstrations

- 1 Waller —The discharge of heat from the muscles of man
  - 2 Gotch —The increased excitability of the sciatic nerve of the cat produced by low temperature
  - 3 Grigorescu —Action of certain poisons upon the central nervous system
  - 4 Cybulski —Method of stimulating muscle and nerve by means of condenser discharges
  - 5 Mares —Nerve excitation by means of varying induced currents due to variations in the rapidity of magneto-induction
  - 6 Wedensky —The most favourable and the least favourable frequency for effective intermittent excitation of nerve by electrical currents
  - 7 Paton —A crystalline globulin obtained from urine.
- In addition the following members showed instruments and models —
- 1 Lahousse —Model of the nerve centres
  - 2 Rosenthal —Calorimeter with recent improvements
  - 3 Laulanić —(a) A universal inscribing manometer  
(b) Apparatus for studying respiratory changes
  - 4 Morat —Recording apparatus
  - 5 Cybulski —The Photohæmotachometer
  - 6 Miescher and Jacquet —A recording chronometer

On Wednesday evening, at the conclusion of the proceedings, the members dined together in the large foyer of the theatre, the President of the Congress, Prof Holmgren, being in the chair

As the Congress is held every three years, the next meeting will take place in 1895, and it was decided that in response to the kind and cordial invitation of Prof Kronecker, the meeting should be held in Berne (Switzerland)

### ELECTRO-METALLURGY<sup>1</sup>

THIS is not the first time a lecture has been delivered here on electro-metallurgy. I find that so long ago as January, 1841, there was a lecture on the subject by Mr Brand

At that time electro metallurgy was very new and very small. It consisted solely of electro plating and electrotype. Electroplating had already begun to be practised as a regular industry, but it was still a question whether the new kind of plating was good, and there were not a few silversmiths who would not offer electro plate for sale because of its supposed inferiority to plate of the old style. That question has long been definitely settled by the fact that every week more than a ton of silver is deposited in the form of electro-plate.

Electrotype in 1841 was not so far advanced—it had not then been taken hold of by the artisan and manufacturer—it was still in the hands of the amateur.

While the voltaic battery was the cheapest source of electric current, electro-metallurgy was necessarily restricted to artistic metal work, or to those applications where the fine quality of the electrotype cast outweighed the consideration of its cost, or where only a thin film of metal was required for the protection of a baser metal from the action of the air.

Within this limited field, the electro deposition of copper, of gold, of silver, of iron, and of nickel, has been carried on commercially with very great success and advantage for almost the whole period of the existence of the art. But beyond these bounds, set by the limitation of cost, it could not pass.

Now, all this is changed—since engineer and electrician have united their efforts to push to the utmost the practical effect of Faraday's great discovery, of the principle of generating electric currents by motive power. The outcome is the modern dynamo, with its result—cheap electricity. The same cause that has led to electric lighting, and to the electric transmission of power, has also led to a very great development of electro metallurgic industry, and not only in the old directions but in new. It is no longer a matter of depositing ounces or pounds of metal, but of tons and thousands of tons. And it is no longer with metal deposition merely that electro-metallurgy now deals, but also with the extraction of metals from their ores, and the fusion and welding of metals. Electro metallurgy has in fact grown so large and many branching, that it is impossible to treat it in a complete manner in a single hour.

One of the latest developments is electric welding. Thus, in one of its forms, that invented by Elihu Thompson, has recently been so thoroughly explained and demonstrated by Sir Frederick Bramwell, that it is not necessary for me to do more than mention it as belonging to the subject.

There is also another species of electric welding—that of Dr Benardos—in which the electric arc is used after the manner of a blow-pipe flame, to obtain the welding of such forms and thicknesses of iron, steel, and other metals, as would be difficult or impossible to weld in any other way, and not only is the electric blow-pipe used for welding, but also for the repair of defects in steel and iron castings, by the fusion of pieces of metal, of the same kind as the casting, into the faulty place, so as to make it completely sound. This new kind of electric welding, as improved by Mr. Howard, is now of sufficient importance to entitle it to the full occupation of an evening. I therefore propose to leave it for detailed description to some other lecturer, and content myself with calling your attention to the interesting collection of specimens on the table, and in the Library (lent by Messrs Lloyd and Lloyd), showing the results of this process.

Even with this curtailment, the extent of the field is still too great, and I must reduce it further by omitting a considerable section of that portion which relates to the extraction of metals from their ores, and, in this connection, only speak of the extraction of aluminium.

But, in the first place, I am going to speak of the deposition of copper, and you will pardon me if I treat it as if you were unacquainted with the subject.

<sup>1</sup> Friday evening discourse delivered by Mr J. Wilson Swan, at the Royal Institution, on May 20

One of the wonderful things about the electro deposition of copper, and in fact any other metal deposited from a solution of its salt in water, is, that bright, hard, solid metal, such as we are accustomed to see produced by means of fusion, can, by the action of the electric current, be made to separate from a liquid which has no appearance of metal about it.

The beginning of every electro deposition process is the making a solution of the metal to be deposited. I am going to dissolve a piece of copper, the most elementary of all chemical operations, but I want to make it quite clear where the metal to be deposited comes from—to show that it is actually in the solution, and actually comes out of it again, for that is an effect so surprising, that it requires both imagination and demonstration to make it evident. There is projected on the screen a glass cell containing nitric acid. Mr Lennox will put into it a piece of copper. He has done so, it quickly disappears, and a blue solution of copper nitrate is formed. Now, if I pass an electric current through this solution, or through some solution of the same kind, which, to save time, has been prepared beforehand, and immerse in it, a little apart from each other—the positive and negative wires coming from some generator of electric current—this will happen: metallic copper will come out of the solution, and attach itself as a coating to the negative wire, and consequently that wire will grow in thickness. At the other wire—the positive—exactly the reverse action will take place. There, if the positive wire be copper, it will gradually dissolve, and become thinner. The quantity of metal deposited on the negative wire will almost exactly equal the quantity dissolved from the positive, and therefore the solution will contain the same quantity of metal at the end of the experiment as at first, but it will not be the same metal, it will be fresh metal dissolved from the positive wire, and the metal originally contained in the solution will have been deposited as metallic copper.

I will show on the screen this process in operation. Here are the two wires I spoke of. The electric circuit, which includes these two wires, is so arranged that on its completion the thick wire will be the positive, and the thin wire the negative. Now please complete the circuit. One wire (the positive) is carrying an electric current into the copper solution, and the other (the negative) is carrying the current away. The solution is conveying the current between the wires, and one of the incidents of the transport of current from wire to wire by the solution, is electro chemical decomposition, or electrolysis, and the result of that is, the deposition, out of the solution, of copper, upon one wire, and the dissolving away, or entering into solution, of copper, from the other. Now it can be clearly seen that the wire that was thick is now thin, and the wire that was thin is now thick.

Imagine the growing wire to be an electrotype mould, and that the deposit of copper which formed on the wire has spread over the surface and formed a nearly uniform film, and that by continuing the process it has become thick, that deposit, stripped from the mould, would be an electrotype.

Or imagine the negative wire to be a thin sheet of pure copper, and the positive wire to be a thick sheet of impure copper, and suppose the action carried on so far that the thin sheet has become thick by the deposition of copper upon it from the solution, and the thick one thin by its copper entering into solution, that case would represent the condition of things in electrolytic copper refining.

Allow your imagination to take one more short flight, and suppose that this is not a solution of copper, but one of silver, and that the growing wire is a teapot to be silvered, and, further, suppose that the dissolving electrode is silver, and you will then understand the principle of electro-plating.

It requires very little explanation to make the ordinary arrangement of electrotyping intelligible. Here is a trough containing sulphate of copper solution. Here is a mould that, through the kindness of Messrs. Elkington, has been prepared for me, this is connected with the negative pole of a battery—and here is a plate of copper connected with the positive pole. When I immerse the mould in the solution—at about two inches from the copper plate—the electrical circuit is completed, and the same electrolytic action that the experiment illustrated will take place. Copper will be deposited on the mould, and will be dissolved in equal quantity from the copper plate, and the supply of copper in the solution will thus be kept up. As it will take a little time to obtain the result I wish to show, I will put this aside for ten minutes or so, and proceed to speak of different applications of this principle of copper deposition.

For the reproduction of fine works of art in metal, electrotype is unapproachable. The extreme minuteness with which every touch of graver or modelling tool is copied by the deposited metal film, separates electrotype by a wide space from all other modes of casting. Even the Daguerreotype image is not too exquisitely fine for electrotype to copy it so perfectly that the picture is almost as vivid in the cast as in the original.

It is this quality that has given to electrotype a rôle which no other process can fill, and, so far, its practical utility is not greatly dependent on the cost of the current. This applies to all those most beautiful things here and in the Library, lent by Messrs. Elkington. These could all have been produced commercially, even if there had been nothing better for the generation of the current than Smee's battery—a very good battery, by the way, for small operations in copper deposition. It gives a very low electro-motive force and that is a defect, but in copper deposition, the half volt or so is generally sufficient to produce, automatically, the required current density.

One of the uses of electrotype, not greatly affected by the cost of deposition, is that of the multiplication of printing surfaces. In these days of illustrated periodicals, electrotype has come more and more into use for making duplicate blocks from wood engravings, which would soon be worn out and useless if printed from direct. It is also employed to make casts from set-up type, to be used instead of ordinary stereotype casts, when long numbers of a book have to be printed, also as a means of copying engraved copper plates. Here are examples of all these uses of the electrotype process. The electro-blocks are lent by Messrs. Richardson and Co., and the copper-plates by the Director General of the Ordnance Survey Office, Southampton.

The plates illustrate the method employed at Southampton in the map-printing department. The original plates are not printed from except to take proofs. The published maps are all printed from electrotypes. Here is an original plate—here the matrix, or first electro, with, of course, all the lines raised which are sunk in the original. The second electro is, like the original, an intaglio. Here is a print from it, and here one from the original plate. Practically they are indistinguishable from each other, and bear eloquent testimony to the wonderful power of electrotype to transmit an exceedingly faithful copy of such a surface.

Nickel has, of late years, come into extensive use for what is termed nickel-plating, as applied to coating polished steel and brass with nickel. Nickel not only has the advantage over silver of cheapness, but also, in some circumstances, of greater resistance to the action of the air.

Another metal, usually deposited in the form of a coating, is iron. The electrolytic deposit of iron is peculiarly hard—so much so, that it is commonly but erroneously spoken of as steel-facing. The deposition of a film of iron upon engraved copper-plates, as a means of preventing the wear incidental to their use in being printed from, has become almost universal. Valuable etchings, mezzo tints, and photogravure plates are thus made to bear a thousand or more impressions without injury. By dissolving off the iron veil with weak acid, when the first signs of wear appear on the surface of the plate, and re coating it with iron, an engraved copper plate is, for all practical purposes, everlasting.

In this case, of course, the film of iron is extremely thin—one or two hundred thousandths of an inch. But it is possible to produce most of the metals commonly used as coatings in a more massive form. Here, for example, is an iron rod half an inch in diameter, entirely formed by electrolytic deposition. I am indebted to Mr. Roberts-Austen for being able to show this, and also for this other example of a solid deposit of iron, and for this beautiful specimen of electrolytic coating with iron. Here also are solid deposits of silver. This drinking cup is a solid silver electro deposit.

These are all departments of electro-metallurgy which would have maintained a perfectly healthy industrial existence and growth without the dynamo, but now I come to speak of a branch of the subject—electrolytic copper refining—which, without that source of cheap electricity, could not have existed. This is the most extensive of all the applications of electro-chemistry, and is rendering valuable assistance to electrical engineering by the improvement it has led to in the conductivity of copper wire.

One of the results of this is seen in the raising of the commercial standard of electrical conductivity.

Ten years ago, contracts for copper wire for telegraphy stipu-

lated for a minimum conductivity of 95 per cent. of Matthiessen's standard of pure copper. Now, chiefly owing to electrolytic refining, a conductivity of 100 per cent. is demanded by the buyer and conceded by the manufacturer.

To show the difference between the past and present state of things in relation to the commercial conductivity of copper, I am going to exhibit on the screen measurements of the resistance of six pieces of wire of equal length and equal cross section—they have been drawn through the same drawplate. Three of the pieces are new, and three are old. The three new pieces are made from electrolytic copper, and are representative of the present state of things. The three old pieces are taken from three well-known old submarine telegraph cables, and they show how very bad the copper was when it was first employed for telegraphic purposes, and how great has been the improvement. I will take No. 1 wire as the standard of comparison. It is a piece of the wire about to be supplied to the Post Office Telegraph Department for trunk telephone lines. It will show the very high standard of conductivity that has been reached in the copper of commerce. I am indebted for it, and for two out of three of the old cable wires, to Mr. Preece. No. 2 wire is made from electrolytic copper, deposited in my own laboratory. No. 3 is also electrolytic copper, but such as is commercially produced in electrolytic copper refining, it has been supplied to me by Mr. Bolton, to whom I am also indebted for wire No. 6—a particularly interesting specimen—it is from the first Trans Atlantic cable—the cable of '58. No. 4 wire is from the Ostend cable of 1860, and No. 5 wire is from the old Dutch cable. These wires are so arranged that I can send a small and constant current partly through any one of them, and partly through a galvanometer. When this is done the result will be a deflection of the spot of light on the scale from the zero point to an extent corresponding to the resistance of the particular wire in the circuit. The worse the wire is, the greater will be the deflection. We will begin with the Post Office sample first. I connect the galvanometer terminals to wire No. 1, you see there is a deflection of ten degrees. I will now shift the contacts to wire No. 2—exactly the same length of wire is included—but now you see there is a deflection of slightly less than ten degrees, showing that this wire has a little lower resistance than No. 1. The difference is very small—it may be 2 per cent.—and 2 per cent. less of it would be required to conduct as well as the No. 1 wire. The next is No. 3. This is Mr. Bolton's wire, and shows a resistance almost equal to the last.

No. 1, 2, and 3 are, therefore, nearly alike, and have a degree of conductivity almost as high as it can possibly be.

Now we come to the three old wires.

We will take No. 4 (the Ostend cable). There, you see, is a great difference. Instead of the spot of light being on the tenth degree, it is upon the eleventh.

We will now try No. 5 (the Dutch cable). That drives the index to 17.

Now I change to No. 6 (the old Atlantic cable), and we have a deflection of no less than 25 degrees. I suppose we may assume that this wire fairly represents the commercial conductivity of copper in 1858, for it is highly probable that for a work so important as the first Atlantic cable every care would be taken in the selection of the copper.

The result of this experiment shows that the copper of that cable was extremely bad as a conductor—that, in fact, it is 150 per cent. worse than the best commercial copper of to-day. In other words, it shows that, in point of electrical conductivity, one ton of the copper of to-day will go as far as two-and-a-half tons of such copper as was used for the cable of '58.

This change is largely due to electrolytic copper refining.

The process of electrolytic copper refining is the same in principle as that which produced the thickening of one of the wires and the thinning of the other in my first experiment. To prepare the crude copper for the refining process it is cast into slabs, these form the anodes, and correspond to the wire which in my first experiment became thin. The cathodes, corresponding to the wire which became thick, are formed of thin plates of pure copper. Here are plates such as are used in electrolytic copper refining works. They are portions of actual cathodes and anodes, and represent the state of things at the commencement, and at the end, of the depositing operation—an operation that takes several weeks to complete, and effect the great change these plates show. In copper refining works an immense number of these plates, each having 6 to 10 square feet of superficial area, are operated upon together in a great

number of large wooden vats containing sulphate of copper solution and a small proportion of sulphuric acid. Electric current from a dynamo, driven by a steam-engine or water-power, is conveyed by massive copper conductors to the vats, arranged in long lines of 50 or 100 or more in series. Thick copper bars connect adjoining vats, and provide a positive and negative support for the plates, which hang in the solution opposite each other, two or three inches apart. During the process the impure slabs dissolve, and at the same time pure copper is deposited from the solution upon the thin plates. The deposition and dissolving go on slowly, in some cases very slowly, for a slow action takes less power, and gives purer copper than a more rapid one. The usual rate is one to ten amperes per square foot of cathode surface. You will better realise what these rates of deposit mean, when I say that one ampere per square foot rate of deposition gives for each foot of cathode surface, nearly one ounce of copper in twenty-four hours, and a thickness of one eighth hundred of an inch, and therefore the production of one ton of copper at that rate in twenty-four hours would require a cathode surface in the vats, in round numbers, of 36,000 square feet. At the higher rate of ten amperes per square foot, which is used where coal is cheap, one tenth of this area would be required.

The importance of the electrolytic copper refining industry, and the extent of the plant connected with it, may be inferred from the fact that, reckoning the united production of all the electrolytic copper works in the world, nearly one ton of copper is deposited every quarter of an hour.

Very little power is required for copper deposition if the extent of the dissolving and depositing surfaces is large, relatively to the quantity of copper deposited in a given time.

Some of the impurities ordinarily found in crude copper are valuable. Silver and gold are common impurities, and these and some other impurities do not enter into solution, but fall down as black mud, are recovered, and go to diminish the cost of the process or increase the profit, and even those impurities which enter into solution are, under ordinary conditions, almost completely separated.

Electrolytic copper refining is both an economical and an effective process. The deposited copper is exceptionally pure. At one time it was supposed that it must necessarily be quite pure, but this is not the case, other metals can be deposited with the copper, but it is not difficult to realise in practice a close approximation to absolute purity in the deposited copper. Here is an example of the deposition of a mixed metal—brass, that is, copper and zinc deposited together, and there are in the Library a number of interesting specimens of mixed metal deposition. These deposits of brass and other alloys show that more than one metal can be deposited at the same time. The great enemy to conductivity in copper is arsenic, and the deposition of arsenic as well as copper is one of the things to be guarded against in electrolytic copper refining. Not only are the chemical characteristics of electrolytically refined copper generally good, but its mechanical properties are largely controllable. Usually electrolytic copper is melted down and cast into billets of the form required for rolling and wire-drawing. This treatment not only involves cost, but the copper is apt to imbibe impurity during fusion, though, if the process is carefully conducted, the deterioration is slight.

But it is evident that the re-melting of the deposited copper is a thing to be avoided if possible, and the question naturally arises, why, now that deposition costs so little, may not the beautiful principle which comes into play in electrolysis, and which enables the most complicated forms to be faithfully copied be taken advantage of to give to plainer and heavier objects their ultimate form?

There are several reasons why this idea is not more frequently acted upon. One is that the process of electrolytic deposition is slow, another, that knowledge of the conditions necessary for obtaining a deposit having the required strength and other qualities, is not very widespread. Moreover, in the electrolytic deposition of copper, and indeed of all metals, there is a strong tendency to roughness on the outside of the deposit, and to excrement growths, the removal of which involve waste of labour and material. These tendencies can to a very great extent be counteracted by careful manipulation and the use of suitable solutions, and they can also be counteracted by mechanical means. This has been done by Mr. Elmore. He remedies the faults I have mentioned by causing a burnisher of agate (arranged after the manner of a tool in a screw cutting

lathe) to press upon and traverse a revolving cylindrical surface on which the deposit is taking place, and while it is immersed in the copper solution. The result is that it is kept smooth and bright to the end of the process.

But the use of a burnisher is not the only means available for the production of a smooth deposit. It was observed in the early days of electro-plating how great a change was effected in the character of the metal deposited by the presence of a very small quantity of certain impurities. It was found, for example, that an exceedingly minute dose of bisulphide of carbon, if put into a bath from which the silver was being deposited, caused the deposit to change from dull to bright.

I have lately had experience of a similar kind with nickel and with copper. I was working with a hot solution of nickel, and up to a certain point the deposit had the usual dead-grey appearance. Suddenly, and without doing anything more than putting in a new cathode I found the character of the deposit completely changed. Instead of the grey, tough, adherent deposit, there was produced a brittle, specular deposit, which scaled off in brilliantly shining flakes of metal. I sought for the cause of this extraordinary change, and traced it to the accidental introduction into the solution of a minute quantity of glue.

By adding gelatine to a fresh nickel solution I obtained the same peculiar bright and brittle deposit that had resulted from the accident. I then made a similar addition to a solution of copper, and when I hit the right quantity—an exceedingly minute one—bright copper, instead of dull or crystalline, was deposited. Here are some specimens. These were deposited on a bright surface, and they are bright on both sides.

Not only is the copper made bright, under the conditions I have described, but, if the proportion of the gelatine be carried to the utmost that is consistent with the production of a bright deposit, it becomes exceedingly hard and brittle. Beyond this point the deposit is partly bright and partly dead, the arrangement of the patches of dead and bright being in some cases very peculiar, and suggestive of a strong conflict of opposing forces.

Before I leave the subject of copper deposition, I may mention that I have found the range of current density within which it is possible to obtain a deposit of reguline metal, far wider than is commonly supposed.

The rate of deposition in copper-refining is usually very slow, and it is one of the drawbacks of the process, since slow deposition necessitates large plant. But rapid deposition necessitates a larger consumption of power, and larger cost on that account, and therefore, there is a point beyond which it is not good economy to go, in the direction of more rapid deposition. Still there are cases, where, if we had the power to deposit more rapidly, it might be found useful to exercise it. The subject of more rapid deposition is also interesting from a scientific point of view, I therefore mention an unusual result I have arrived at in this direction.

Taking as one extreme, the slow rate of deposit, of one ampere per square foot of cathode—a rate not infrequent in copper-refining, I have found that the limit in the other direction is not reached by a rate of deposit one thousand times faster. I have produced, and I hope to be able to produce before you, a perfectly good deposit of copper, with a current density of 1000 amperes per square foot of cathode.

This cell contains a solution of copper nitrate with a small proportion of ammonium chloride. The plate on which I am going to produce a deposit of copper has an exposed surface of 21 square inches. Opposite, at a distance of one inch, is a plate of copper. When I close the circuit, a current of 140 amperes is passing through the solution. I continue this for just one minute. Now I wash it and remove the outer edge so as to detach the deposit, and as you see, I have a sheet of good copper—an electrolyte.

To have produced a deposit of this thickness at the ordinary rate used in electrotyping operations would have occupied more than an hour.

In this experiment an extreme degree of rapidity of deposition has been shown. I do not intend to suggest such a rate of practical value. But it is at least interesting, as showing that the characteristic properties of copper are not less perfectly developed when the atoms of metal have been piled up one on the other at this extremely rapid rate than when there is slower aggregation.

I think it probable that a rate of deposit intermediate between this rate and the usual one of about 10 amperes per square foot may frequently be useful, for no doubt the slowness of the rate

of deposit has often prevented electrotype from being made use of where, if the rate could have been increased ten times, it might have been used with advantage.

Here are some thick plates, deposited at the rate of 100 amperes per square foot. They are as solid and as free from flaw as plates deposited ten times more slowly.

I said that electrolytic copper refining owed its existence to the discovery and improvement of the dynamo, and that other electro-metallurgic industries had originated from the same cause. One of these industries is the electrolytic production of aluminium.

When Deville produced aluminium by the action of sodium on aluminium chloride, exaggerated expectations were entertained of the great part it was about to play in metallurgy. It was very soon found that aluminium had not all the virtues that its too sanguine friends had claimed for it, but that it had a great many most valuable properties, and, given a certain degree of cheapness, a number of useful applications could be found for it. Some of these are suggested and shown by the various articles made of aluminium, kindly lent by the Metal Reduction Syndicate, and metallurgical research is rapidly extending our knowledge of its importance in connection with the improvement of steel castings, and the production of bronzes and other alloys of extraordinary strength. The cost of aluminium produced by Deville's process was too great to permit of its use on any large scale for these purposes.

After Davy demonstrated, by the electrolytic extraction of potassium and sodium, the power of the electric current to break down the strong combination existing between the alkaline metals and oxygen, it seemed natural to expect that aluminium would also be reduced by the same means. But Davy did not succeed in producing any appreciable quantity of aluminium by the electrolytic method. Deville and Bunsen were more successful, but they did not possess the modern dynamo that has made all the difference between the small experimental results they achieved and the industrial production of to-day, a production now so large that I suppose every day it amounts to at least one ton, and has resulted in a very great reduction of the price of the metal.

There are two electrolytic processes at work. One is the Hall process—employed at Pittsburg, and at Patricroft, Manchester—and now in experimental operation here. The other, the Herault process, worked at Neuhausen, is not greatly different from the Hall process—the shape of the furnace or crucible is different, and the composition of the bath yielding the aluminium may be different, but in all essentials these two processes are one and the same. They depend on the electrolysis of a fused bath, composed of cryolite, aluminium fluoride, fluor-spar, and alumina. In the Hall process this mixture is contained in a carbon lined iron crucible—the cathode in an electric circuit, and between which and the anode—a stick of carbon immersed in the fused bath—a difference of potential of 10 volts is maintained. In carrying out the process on a manufacturing scale, there are many of these sticks of carbon to each bath. Here, in our experimental furnace, there is only one.

The heat developed by the passing of so large a current as we are using (180 amperes) through an electrolyte of but a few inches area in cross section, is sufficient to melt and keep red-hot the fluorides in which the alumina is dissolved.

The electrolytic action results in the separation of aluminium from oxygen. The metal settles to the bottom of the pot, and is tapped or ladled out from time to time as it accumulates. The oxygen goes to the carbon cylinder, and burns it away at about the same rate as that at which aluminium is produced. It is only necessary to keep up the supply of alumina to enable the operation to be continued for a long time. I mean, of course, in addition to the keeping up of the current and the supply of carbon at the anode.

By far the greater part of the cost of aluminium obtained by electrolysis is the cost of motive power. 20 horse-power hours are expended to produce 1 pound of aluminium. Therefore it is essential for the cheap production of aluminium to have cheap motive power.

There is one feature about the Neuhausen production of aluminium which is very striking, and that is the generation of the electric current by means of water power derived from a portion of the falls of the Rhine at Schaffhausen.

The motive for making use of water power is economy. But, apart from that, it is interesting to see water replacing coal, not only in the production of power, but also in the production of the heat required in a smelting furnace.

Here is the Hall apparatus on a small scale. It is simply a carbon lined iron crucible, and a thick stick of carbon. As already mentioned, the crucible is the cathode, the stick of carbon the anode.

As the process takes time to get into full operation, it was commenced some hours ago, and at the rate at which it has been working we should by now have produced several ounces of aluminium. In beginning the process the charge has first to be melted. This is done by bringing the carbon stick into contact with the bottom of the crucible, so as to allow the current to pass from carbon to carbon to develop heat between the electrodes.

The alumina compound, which, when melted, forms the bath, is added, in powder, little by little, and, when sufficient is melted, the carbon stick is raised out of contact with the bottom, and the electrolytic action then commences.

I will now ask Mr. Sample to empty the crucible and let us see the result of the operation, and while he is doing so I take the opportunity of expressing my very sincere thanks for his having so kindly and so successfully carried out this most interesting demonstration of the latest and one of the most important of all the applications of electricity to metallurgical operations.

Here is the result of our experiment. It is not very large certainly, but it is quite enough for our purpose, which is to illustrate the principle of a newly developed electro-metallurgical industry directly derived from discoveries made at the Royal Institution.

#### MOUNT MILANJI IN NYASSALAND

HIDDEN in the recesses of one of the recently issued Parliamentary Papers (Africa, No 5, 1892) will be found a very interesting report on the mountain and district of Milanji, in British Central Africa, by Mr. Alexander Whyte, F.Z.S., one of Mr. Commissioner Johnston's principal assistants in the task of ruling and developing the new British Protectorate of Nyassaland. Mr. Whyte was sent to Milanji by Mr. Johnston in October last, and dates his report from the "Residency, Zomba, British Central Africa," in the month following. Milanji is a large mountain mass in the extreme south east corner of Nyassaland, drained on the west by the head waters of the Ruw, one of the affluents of the Shire, and on the east by the Lukuga and other smaller streams, which run into the Indian Ocean north of the Zambesi. It is described by Mr. Whyte as an isolated range of, for the most part, precipitous mountains, the main mass forming a huge natural fortress of weather-worn precipices or very steep rocky ascents, sparsely clothed with vegetation. Many of its gullies and ravines are well wooded, and in some of them fine samples of grand African virgin forest are met with. Mr. Whyte's ascent, on the 20th of October, was made up the south east face of Milanji, over steep grassy hills and across rocky streams, full of large water-worn granite boulders. Further on precipices were encountered, and it was necessary to clamber up, holding on by tufts of grass, roots, and scrub, after which a wooded gorge was entered, and welcome shade was obtained from the forest trees.

Here an interesting change in the vegetation was at once perceptible, the plants of the lower slope being mostly replaced by other species. These in many cases approached the flowers of temperate climes, such as brambles and well-known forms of *Papilionacea* and *Compositæ*. Ferns, too, became more numerous, and now and again were encountered perfect fairy dells of mosses, Selaginellas, and balsams, with miniature water falls showering their life giving spray on the little verdant glades, while overhead hoary lichens and bright festoons of elegant long-tasselled Lycopods hung from the moss covered trees. After they had passed through some dense thickets of bamboo, and climbed up an ugly barrier of precipitous cliffs, another hour's ascent, the latter part of which was through a steep grassy glen, brought Mr. Whyte and his companions to the highest ridge of Milanji.

Hence was a splendid view over rolling hills of grassy sward divided by belts of dark green forest, and the climate was found to be delightfully cool and bracing, with a clear dry atmosphere of about 60° Fahr. Altogether two weeks were spent at three different sites on this high plateau, and good collections of its natural history were made, although rain and mist occasionally interfered with the operations of the naturalists.

The flora of the mountain proved to be of great interest,

being quite distinct from that of the surrounding plains, and even from that of the lower slopes. Tree ferns were found to attain a great size in the damp, shady forest, and one was measured 30 feet in height and 2 feet in diameter at its base. The display of wild flowers is described as "gorgeous." Creamy-white and yellow *helichrysums* mingled with purple and blue orchids and *irises*, and graceful snow-white anemones were all blooming in wild profusion, and rearing their heads from a bed of bright green grassy sward. But the most striking botanical feature of the Plateau of Milanji was the cypresses formerly apparently quite abundant, but now confined to a few of the upper ravines and valleys, where the annual bush fires, which take place in the dry months of August and September, cannot reach them. In some places hundreds of these giant trees thus destroyed lay prostrate, piled one above another, in every stage of destruction. One of these dead conifers was found to measure 140 feet in length and 5½ feet in diameter at 5 feet from its base. The foliage of this cypress is juniper-like. The timber, of a dull reddish-white colour, is of excellent quality and easily worked. Ripe cones of this fine tree were procured, and, as stated in a subsequent letter, have already germinated in the experimental garden at Zomba.<sup>1</sup>

The fauna of the mountain was found to be of nearly equal interest to the flora, but in the short space of time available it was not possible to make so nearly a complete collection. Raptorial birds were very scarce, but *Passeres* were plentiful. The grassy lands of the summits were tenanted by a small dark brown quail, a pipit, two grass-warblers, and the ubiquitous great billed raven (*Corvus albicollis*), which, however, was not so numerous as on the plains below. In the adjoining forest bird life was abundant. Bulbuls, fly-catchers, warblers, finches, and honey-birds joined in chorus in celebrating the springtime and nesting season, which was then in full progress. Altogether about 200 specimens of birds were obtained. Of mammals few were met with. The beasts of prey consisted of the leopard, the spotted hyæna, the serval, and an ichneumon. Examples of three species of *Murids* were also obtained, and a little antelope, probably of the genus *Neotragus*, was observed, but not procured. A few snakes were likewise met with.

As regards the question of establishing a sanatorium on the Milanji Plateau, to which special attention had been directed, Mr. Whyte has no hesitation in saying that the climate of this district contrasts very favourably with that of some of the hill stations in India and Ceylon. The year is pretty equally divided between wet and dry months, the former lasting from November till May, while the other six months are stated to be fine, clear, and bracing, the thermometer at night in the months of May, June, and July occasionally falling below the freezing point. In the month of October the air was found to be delightfully pure and balmy. We believe that steps have already been taken to build a small station on Milanji, but to render this of much use it will be necessary to form a road to it from the falls of the Ruw up the Lutshenya valley. This could be made with fairly good gradients, and would be of great advantage as an outlet for the cypress timber, which now lies useless and decaying in the forest.

We are pleased to be able to add that Mr. Whyte's collections above spoken of, along with others from Mount Zomba, have already reached London, and are in the hands of Mr. Slater, to whom Mr. Johnston has entrusted the task of getting them worked out and described. Mr. Oldfield Thomas has already commenced to determine the mammals, Captain Shelley will name the birds, and Mr. Boulenger, it is believed, will undertake the examination of the reptiles and batrachians. The plants will be examined in the Botanical Department of the British Museum, in which institution Mr. H. H. Johnston has directed the first set of specimens in every department to be deposited. The zoological results will be published in the "Proceedings" of the Zoological Society of London.

#### OBSERVATIONS OF THE PLANET MARS<sup>1</sup>

I OUGHT to have written to you before on the subject of the planet Mars, which I have been studying for over four months with our great equatorial. My great desire to verify the

<sup>1</sup> Some cones of this supposed "Cypress" have also reached the Botanical Department of the British Museum, and have proved to belong to a Conifer of the genus *Widdringtonia*, probably of a new species. But this point cannot be definitely settled until more perfect specimens of the tree have been received.

<sup>2</sup> Letter from M. Perroux to M. Faye, *Comptes rendus*, September 3.

extraordinary phenomena to which I alluded in my last letter may account for this

Besides, I have gained nothing by waiting, and at the present time, after successive delays which I much regret, I am hardly further than I was a month ago. Owing, perhaps, to the images being less satisfactory, or to the phenomenon in question not having recurred, nothing has been added to my first observation.

The phenomena alluded to are brilliant projections, comparable in colour and brightness to the southern pole cap, observed on three different occasions—viz., June 10 and July 2 and 3, on the western limb of the planet.

The last time, July 3, I was able to observe the several phases of this singular appearance. On that day the luminous point began to emerge on the edge of the disc at 14h 11m (local astronomical time), very faint at first, then I saw it gradually increase, pass through a maximum, and then diminish, to disappear finally about 15h 6m. The facts would not have been different had it been a case of an elevation of the surface of Mars traversing the illuminated edge of the disc by the simple effect of the rotation of the planet. The phase which affected the western limb of the planet at that time, could only modify it in amount and in duration. The previous night, July 2, I had seen the crescent in a phase approaching the maximum, at 14h 10m, and I was able to follow the bright point up to its complete disappearance at 14h 40m.

On July 2 and 3 the things happened in the same part of the disc, about the 50th parallel of latitude, and with a retardation of half an hour against the previous day, as usual for a thing taking place in the same region of the planet.

The first observation of this kind goes back as far as June 10, when it lasted from 15h 12m to about 16h 17m. This time the bright point occurred in the vicinity of the 30th southern parallel, probably in the southern portion of the isthmus Hesperia of Schiaparelli's chart.

I may add that during these observations the portion of the disc adjoining the small protuberance has always appeared to me slightly deformed and as if raised.

Such are the facts. I shall not attempt to interpret them. They presented themselves with such clearness that it is hardly possible to consider them as the result of any illusion.

On the other hand, since it is a question of projection beyond the disc of at least one or two tenths of a second of arc, that is to say, of phenomena at a height of more than 30 or 60 km, one feels overwhelmed by such numbers, to which we are not accustomed on our globe, and it is undoubtedly luminous phenomena only which could explain heights like that.

The southern snow cap has been the object of several measurements, which will be published with the drawings of this opposition. This cap has notably diminished in the last two months; it is, in fact, shifting, it is traversed by at least two black lines, a kind of crevices analogous to those which I announced in 1888 in the case of the northern cap. The first of these lines was seen at the end of June, the second on August 8.

The outline is now more irregular than in the past, in particular there is seen, between the meridians of 300° and 0° (Schiaparelli's map), a deep black hollow which grows steadily.

Although the actual conditions are not very favourable for the canals (at least for a portion of them), several are well visible, some are apparent enough to convince the most prejudiced observers.

Two of our drawings of the Great Syrtis, made at widely different dates, indicate some slight changes in the most northerly portion of this sea. They are no doubt due to mists and clouds, which have sometimes appeared to me to invade the northern regions on the east of this Great Syrtis, hiding the canals which traverse them, and only allowing us to see their most southern portion.

Our drawings of the Lake of the Sun, when compared with those of M. Schiaparelli, also indicate some changes of detail in the aspect of the lake itself and of the seas and canals surrounding it.

The most interesting observation of this month is the one I have made, on August 6, of a very bright point placed precisely a little to the north of this Lake of the Sun. This point, which struck me by its extraordinary radiance, could not be seen the next day; if it still existed—the images were not so good as the previous night—it was certainly much less luminous.

This phenomenon, and the analogous phenomena sometimes

noticed on the surface of the planet, are perhaps not without some relation with the appearances of the limb which I have announced. Future observations will no doubt inform us on this subject.

I should perhaps have still deferred sending this letter if I had not, within the last few days, received from Mr. Newcomb the extract of a journal, in which it is reported that the Lick astronomers have also observed the luminous projections on the edge of the disc.

I may add that in the beginning of July I had imparted my observations to M. Andre, director of the Lyons Observatory, who happened to be on a visit to Mont Gros, and whom I had invited to come on the 5th and verify the strange appearances which I had told him of. Unfortunately, the sky remained obscured all night, and my project could not be carried out.

## SCIENTIFIC SERIALS

THE *American Meteorological Journal* for August contains — Synoptical sketch of the progress of Meteorology in the United States, by W. A. Glassford, and reprinted from the annual report of the chief signal officer for 1891. From this summary it appears that Isaac Greenwood, a professor of mathematics in Harvard College, prepared a form for observations at sea in 1728, thus anticipating the efforts of Lieut. Maury by more than a century. Observations of temperature and rainfall were begun in Charleston in 1738, and were soon followed by several other series. In 1817, J. Meigs, Commissioner of the General Land Office, proposed to Congress the establishment of meteorological stations at each of the land offices, and as this proposal was not adopted, he started a voluntary system among his subordinates, and supplied registers for the purpose. This system lasted until his death in 1822. The next service was established by the Surgeon General of the Army, in 1819, and was maintained, with modifications, until 1854, when the records were handed over to the Smithsonian Institution, and in due time were transferred to the Signal Service. The Patent Office, of which agriculture formed a division, and the Coast Survey also manifested great interest in the science. The article contains a good review of the labours of the principal American meteorologists.—Note on winter thunderstorms, by Prof. W. M. Davis. He asks whether the convectional origin of thunderstorms in summer implies a like origin for thunderstorms in winter, even though they occur then at night, and he explains the reasons which seem to favour this supposition.—Objections to Faye's theory of cyclones, by W. C. Moore. The writer attempts to show why the generally accepted theories seem to him preferable to those brought forward by M. Faye. The discussion is to be continued in a future number.—Artificial rain, by E. Powers. The writer is the author of a work entitled "War and the Weather," and he supports the view that rain can be artificially produced, and endeavours to refute the objections urged by Prof. W. M. Davis and others.

Wiedemann's *Annalen der Physik und Chemie*, No. 8.—On the refraction of rays of great wave length in rock-salt, sylvine, and fluorspar, by H. Rubens and B. W. Snow. A series of bolometric researches concerning the infra red rays, to determine the refractive indices of the three substances for light of various wave-lengths up to  $\lambda = 80,000$ . Fluorspar, though showing a lesser dispersion than the other two in the visible portion, excelled them enormously in the infra red, hence it is specially suited for the production of prismatic heat spectra.—Reflection and transmission of light in certain isotropic structures, by H. E. J. G. du Bois. An isotropic structure is a portion of matter, generally plane, in which it is possible to fix upon an optically favoured direction. This can be due to its coarse macroscopic or its molecular and microscopic structure. In both cases vertically incident or reflected light will be acted upon differently according as its plane of polarization is parallel or normal to the favoured direction. This action is in general unequal as regards both the amplitude and the phase of the two components. The objects experimented upon were, in the first class, bright silver wire gratings, platinum film gratings, scratched metal reflectors, and scratched glass gratings, in the second class, crystals of cobaltine and pyrites, and a loaded steel mirror. In the case of the silver wire gratings it was found that light polarized in a plane normal to the direction of the wires was let through in greater intensity

than that polarised parallel to them. The contrary was observed in scratched glass gratings, while a scratched metal mirror reflected 4 per cent more perpendicular than parallel light.—The limiting index of refraction for infinitely long waves, transformation of the equations of dispersion, by E. Ketteler. The determination of the limiting coefficient of refraction is shown to be impossible, both in practice and by the current theory. Another form of the equation of motion of light is worked out, which promises a solution of the problem.—On the electricity of waterfalls, by Ph. Lenard. Numerous observations and experiments concerning the electricity developed by water falling in drops, jets, or waterfalls have led to the following general conclusions. Drops of water falling on to water or a wetted body generate electricity. Water is electrified positively, air escapes negatively electrified from the foot of the fall. Jets breaking up into spray make the electrification more apparent. Slight impurities in the water diminish the effect considerably. Other liquids and gases also produce electrification, but differing in intensity and sign. The essential conditions of electrification are the collisions among the waters themselves and against the wet rock. The friction against the rock and the fall of the earth-potential are of secondary importance, while no effect is due to the waters fall through air and its dispersion in it. The author explains these phenomena by the sudden diminution of the water surface, and the convection of negatively charged air away from the foot of the fall. A jet of water falling from an insulated tank into an insulated pail electrified the latter positively, while the negative electrification of the surrounding air grew to several hundred volts. A steady increase of potential was also produced by drops of water falling at the rate of two per second. Sparks were sometimes obtained from waterfalls, and in all cases the air was found to be negatively charged, though this charge was diminished if air bubbles were driven under water.—Note on a phosphoroscope with spark illumination, by Ph. Lenard. This ingenious apparatus consists of a Ruhmkorff coil with condenser and mercury interrupter, fitted with terminals of strip zinc or zinc wire, in order to produce as much ultra-violet and phosphorescent light as possible. The arm of the mercury interrupter is prolonged, and carries at its end a rectangular shade of black paper, large enough, in its mean position of rest, to hide the spark and the terminals. Hence when the coil is working the sparks are not seen. But if a phosphorescent substance be placed behind the terminals, it continues to glow when the screen is at its highest or lowest position, thus producing the impression as if the screen, which appears perfectly stationary, were only transparent for phosphorescent light. For lecture purposes the apparatus is placed behind a screen with an opening as large as the black paper shade. The results are in general the same as those of Becquerel's phosphoroscope. A brilliant green light is obtained from pentadecylparatolylketone. The interval between illumination and observation is  $\pi/10$  second.—On the production and observation of very rapid electric oscillations (continued), by A. Toepler.—On the use and mode of action of the telephone for electric null methods, by A. Winkelmann.

# SOCIETIES AND ACADEMIES

## PARIS

Academy of Sciences, Sept. 5.—M. de Lacaze-Duthiers in the chair.—Note on the treatment of cancer and cholera by the testicular liquid, by M. Brown-Séquard. Some recent results seem to indicate that the testicular liquid, already proved to be efficacious in cases of pulmonary tuberculosis, leprosy, and other diseases, also exerts a beneficial influence on cancer patients. This is not due to any action upon the microbes producing the disease, but to an augmentation of the powers of the nervous system, which is enabled to resume its normal functions by subcutaneous injections of the extract. M. Ouspensky, a military physician sent by the Russian Government to study and cope with the cholera in the Caucasus, is reported to have "cured every patient" by this method. Whether or not this be true, there is no doubt that the injections strengthen the nervous system, which is much exhausted even in convalescents.—Observations of the comet Denning (1892, II) made at the great equatorial of the Bordeaux Observatory, by MM. G. Rayet, L. Picart, and F. Courty, reported by M. G. Rayet.—Observations of the planet Mars, by M. Perrotin [see p. 482].

NO. 1194, VOL. 46]

—Reappearance of the leafy celandine of Pometerre, by M. D. Clos.—Observations of the new comet Brooks (C. 1892), and of the new planet Wolf, made at the Observatory of Paris (west equatorial), by M. G. Bigourdan.—Observation of the comet Brooks (August 28, 1892), made with the Brunner equatorial (o 16) of the Lyons Observatory, by M. G. Le Cadet.—On the calculation of inequalities of a high order, by M. O. Callandreau.—On a new form of induction apparatus, by M. J. Morin. The induction coils usually employed in electrotherapy are constructed with two cylindrical and concentric bobbins, sliding one over the other, and giving the maximum effect when the coils coincide along their whole length. There is a difficulty in reaching the zero by a regular diminution of the current. This is obviated in the apparatus as constructed by M. Morin. The conducting wires are wound on two flat concentric rings provided with channels of appropriate form. When an intermittent current is sent through the outer ring induced currents will be obtained from the inner ring. The effect will be greatest when the two rings are in the same plane. If one of these rings be turned round a diameter common to both the induced current will gradually diminish, and will vanish when the one ring is at right angles to the other. This arrangement could be employed for obtaining alternate currents by sending a continuous current through one of the rings and rotating the other. A sinusoidal current would be thus generated, the effects of which have been lately much appreciated in electrotherapy. For electric lighting the number of alternations might be increased by transforming the currents into induced currents of a higher order, by Prof. Henry's method, utilized recently by M. Tesla.—Removal of the thyroid in the white rat, by M. II. Cristiani (Geneva). The apparent immunity of the rat from the fatal effects of the removal of the thyroid is shown to be due to the rapid regeneration of this organ. If the extirpation is total, death, otherwise inevitable, can be averted by grafting the organ in the peritoneum.

## A 5-SENSATION THEORY OF VISION

*Color Vision* By E. Hunt (Glasgow John Smith and Son, 1892)

THE author entitles his work, "An essay discussing existing theories, explaining views hitherto incompletely published, and comprising illustrated descriptions of important new experiments." We shall now proceed to see how the promise conveyed by the title is fulfilled. In the early pages of the book he makes the statement that there are five colours which are distinct sensations, viz., red, yellow, green, blue, and purple. The last, however, he is rather less certain about as conveying his meaning, but finally adopts the name after explaining what he designates by purple. These are the five colours of a 5-colour theory which he propounds, all other colours being mixtures. He has felt, however, that it is no use to bring forward a theory unless he demolishes those other theories which block the way. His examination of these last is chiefly confined to that of Young, which accounts for colour-vision on the assumption that there are only three colour sensations—a number which is a minimum when the fact is remembered that all colours can be produced by a simple colour, or by a mixture of two or three of the colours which are considered to be primary colours. His criticism of the theory is mostly confined to a paper published by Clerk Maxwell thirty years ago, and he scarcely refers to any evidence in its support which has been brought to light in more recent years. Mr. Hunt has entangled himself in mixing up colour and colour sensations together, and has forgotten that in Clerk Maxwell's papers three colours were chosen empirically as approaching the colours which are perceived when the three fundamental sensations are stimulated. Later work has shown that the colours thus shown are not representative of the fundamental sensations. No one, for instance, would say that any green in the spectrum was the colour evoked by the stimulation of the green fundamental sensation, for it is well known that, according to the theory, at every part of this region of the spectrum all three sensations are stimulated, and the nearest approach that a retina possessing normal sensations could make to perceiving this one sensation, would be when the colour evoked was mixed with a percentage of white, rendering the colour impure. We may here parenthetically remark that it is too late for Mr. Hunt to quarrel with the designations of the colour constants, for they are accepted terms. "Impure," for instance, may be an objectionable term to apply to a colour when mixed with white, but as what is meant by it is understood, it can only be used in that sense. The position of the colour which stimulates only the red fundamental sensation is fairly well known, being near to the red lithium line. The position of the colour which stimulates the violet fundamental sensation is still not absolutely settled, but it cannot be very far from the G line of the solar spectrum. Moreover, recent researches show that at the extremities of the spectrum only a red or a violet sensation is stimulated, any change in colour observed being due to a slight admixture of white light, which is derived

from the imperfect transparency of the prisms or reflecting surface of the grating. The colour, for instance, near G, when mixed with a small percentage of white light, in excess of that already mixed with it, takes a violet hue, a colour which is associated with the most refrangible part of the spectrum. As the luminosity of this part is very much less than that near G, the extra percentage of white light required to form this hue is always present. The colour of any ray of the spectrum can be almost entirely freed from the white light derived from the prism by placing another prism in the path of such rays, after passing through a second slit. In an eye-piece or on a screen, the ray will be seen as a well-marked line lying in a faint continuous spectrum. Again, the references to the sensations stimulated in the various types of colour-blind people are not described in any detail, though the evidence which is derived from an examination of their vision is of the greatest importance for the Young or any other theory. The author gives most undue weight to colour diagrams. Colour triangles or circles are not intended to be the basis of a theory, but simply as illustration of it. It is quite possible that Clerk Maxwell's diagrams would not tally with those based on König's observations, nor should they do so. In fact a diagram may be drawn to illustrate any theory, as the author himself has done to illustrate his own.

In animadverting on Clerk-Maxwell's colour equations, the author, it may be remarked, has himself made a mistake as regards certain reductions to be given to the intensities of different colours. The equations are right as they stand, when it is remembered that Maxwell chose to adopt certain arbitrary units which he carried throughout them all.

The author in one place endeavours to prove the superiority of a 5-colour theory over a 3- or 4-colour theory, by narrating what is seen when a spectrum is formed with—what comes to—a very wide slit to the collimator. Practically he shows that this wide slit may be supposed to be made up with narrow slits, and that the spectrum formed when the wide slit is used is made up by the overlapping of the spectrum formed from the narrow slits. He then adds up the colours (or colour sensations) as follows—

$$\begin{array}{r}
 R-G-P \\
 R-G-P \\
 R-G-P \\
 R-G-P \\
 \hline
 R-y-W-W-b-P
 \end{array}$$

With the 4-colour theory he has five rows for addition, and with the 5-colour theory he has six rows. The last gives as the result  $R-2O-3Y-4b-W-W-4pe-3B-2v-P$ , where red, orange, yellow, lemon, white, peacock, blue, violet, and purple are denoted by the letters used as the sum of the additions. He remarks "that the results obtained for the 3-colour and 4-colour theories do not agree with what is actually seen with a prism." We can well believe it! But why he confines the colours to be added up to the number of colours in the theory we are at a loss to understand. It may be taken for granted that in employing this method of proving a theory, that theory which annexes the greatest number of primary colours will give results which are closer to what is seen than even the 5-colour theory.

As to the experiments which are "new and important," there is no doubt that there is one which will prove to be highly important if it can be always repeated to give the same results under conditions which bear rigid examination. The experiment is described as follows:

"Very many years ago I showed experiments with rotating discs, which proved that 'persistence' does not (at any rate, wholly) take place in the way previously supposed, in the retina, or in the individual parts sensitive, as I maintain, variably sensitive, to light and colours. In one of the experiments I refer to, a brightly coloured disc was covered by a black disc having sector shaped openings, such as to render the entire disc area half black and half coloured. When the discs are rotated at a suitable speed, under a strong light, the entire rotating disc appears more brightly coloured than an entire disc placed near the rotating disc. Thus, the colour effect of a disc, half of which is covered by black sectors, is by rotation made equal to or greater than that of an entirely uncovered disc of the same colour."

This one experiment would have caused a good deal of anxiety to those who have been at work at the general theory of vision had they known of it. Fox Talbot, Plateau, and others would have had to amend their papers—for the "persistence of vision" would evidently not obey the law which they adopted after submitting it to such experimental proofs as they could devise. Other experiments which the author brings forward as confirmatory of the 5 colour theory, it seems to the writer can be equally well explained by the 3-sensation theory, and probably by that of Hering.

In conclusion, it seems safe to say that these two last rival theories have not been overthrown by the work under review. Both have their weak points, but the number of them has not been increased by the exponent of the 5-colour theory.

#### ELECTRICAL RULES AND TABLES.

*A Pocket-book of Electrical Rules and Tables.* By John Munro, C.E., and Andrew Jamieson, M.I.C.E., F.R.S.E., &c. Eighth Edition, Revised and Enlarged. (London: Griffin and Co., 1892.)

JUST eight years ago we reviewed the first edition of this electrical *vade mecum*. The fact that we have now to notice the eighth edition is abundant proof that it has been found of service by the electrical public. That it deserved well of those for whom it was compiled there can be no doubt. The authors have been most active in collecting information from all sources, and in extending the work so as to keep the information contained in it fairly representative of the current state of industrial electricity. Since the first edition it has been almost doubled in size, and much very important matter has thereby been added.

A special feature of the book as it now stands is the short accounts of various branches of electrical engineering which have been contributed by specialists. Such are Dr. Thompson's chapter on dynamo machinery, Mr. Kapp's account of transformers, and Prof. Ewing's sketch of magnetic measurements. These are very valuable, and add much to the authoritative character of the work as a guide to engineers more especially concerned with electric lighting and transmission of power.

NO. 1195, VOL. 46]

When the first edition appeared we noticed a number of points in which we thought the book required amendment. Looking over the present edition, we have been struck with the very considerable improvement which has been effected in point of precision and accuracy. But we have again met with some passages in which we fancy the work may be still further improved.

First, on p. 10, we were not able to see before, and we do not see yet, what the fact that the dimensions of resistance in electromagnetic units are those of velocity, has by itself to do with the velocity  $v$ , which is the ratio of the electromagnetic to the electrostatic unit of quantity of electricity.

At p. 15 it might have been well to mention the convergence of all the latest absolute determinations of the ohm upon something like 106.3 cms. as the length of the column of mercury, representing it according to the usual specification.

At p. 42 definitions of the pound avoirdupois and standard kilogramme are given, in which the precise temperature and pressure of the atmosphere at which the weights of the standard lumps of platinum are a pound and a kilogramme respectively are carefully specified. We should like to know why there is not a reference to the hygrometric state of the atmosphere as well.

With regard to the statement with respect to density, at p. 43, it is not usual, we think, to define density otherwise than as mass per unit of volume. It is therefore a quantity of dimensions  $ML^{-3}$ , whereas specific gravity is a mere numeric. In cases in which specific gravity and density are numerically the same, there is still this essential difference in nature between the two quantities.

Of course, the same word *density* is used in a peculiar sense, frequently, when applied to gases, and our experience shows that nothing has a more confusing effect in the mind of an elementary student of physics and chemistry than this double use of the word. It would be well to insist, as is often done by careful teachers, that it is *relative density* that is here meant, and not density in the ordinary sense.

With respect to the velocity of sound in air (p. 50) it might be as well to notice that it depends upon the temperature of the air.

At p. 127, under the heading "Impedance," impedance in its proper technical sense as  $\sqrt{R^2 + \pi^2 L^2}$  is not defined. The definition is given elsewhere in the book, but there is no clue to it in the index. In the last formula the exponential  $e$  has fallen out from before its exponent. Here we might remark that in a book of this kind, where space is of great importance, and especially with such lumbering exponents as  $-\frac{RT}{L}$ , the use of the *solidus* notation would be a great improvement.

The authors will not think us inappreciative in making these remarks. In a work dealing with such a multifarious set of topics it is difficult even in several editions to completely eliminate error, and we have made these notes (and some others) in case the authors may care to make use of them. As we have said, the book is a useful and handy synopsis of electrical information of all kinds, and is very worthy to take the place which it seems to be being accorded to it, of the electrical *Mohs-work*.

## THE MOTHS OF THE WORLD

*A Synonymic Catalogue of Lepidoptera Heterocera (Moths)* By W F Kirby, F L S, F F S, &c Vol I Sphingides and Bombyces (London Gurney and Jackson, 1892)

THE publication of the first volume of Mr Kirby's Catalogue of Heterocera cannot fail to be regarded as a great event amongst students of exotic moths, and should mark an epoch from which is to commence the great work of reducing the vast amount of material they have to deal with to some kind of system and order, from the state of chaos produced by the greater number of those who have taken up the subject continuing to describe innumerable species, forms, and varieties, without any systematic study or attempt to define the limits of the families and genera they placed them in. So vast and scattered was the literature on the subject that it was almost hopeless to attempt to discover even how many species had been described in any given genus, or to say with any certainty that the forms to be dealt with had not been described by other authors, and if the subject in hand was the study of a local fauna, and not the monographing of a group, the only plan it was possible to adopt was to place the species in approximately the right genus and trust more or less to chance, according to the availability of large collections for consultation, that they had not been described elsewhere. Students will now have no such excuse for inexact work, and, up to the end of the numerous and very remotely connected groups of families known as the Bombyces, will have a complete and easily consulted catalogue of all described species, with the localities they come from, so that they will be able to see at a glance to which species the forms they are trying to identify are most likely to belong, and having full references to the books in which they are described their labours will be lightened by almost half, as students of the European fauna who have had Staudinger's catalogue to help them will fully appreciate. No one but Mr Kirby who has lived his life among the books on the subject, and has been collecting his materials for the last twenty years, as he tells us in his preface, could have made the catalogue as complete as he has done, and though it is of course impossible that such a volume could have been put together without a few errors and omissions creeping in, yet some months of work with the advantage of being constantly able to borrow the proof sheets has shown how extremely few these are.

As the arrangement adopted is in the main that of the British Museum, or of some well known and approved works on special groups, and as there is also an index to the genera, there should be no real difficulty in finding the species required, and since the complete index to species and genera will take up one out of the five volumes required to complete the catalogue, it is obviously impossible that there should be a specific index to each volume. It is to be hoped that Mr Kirby will be able to bring out the other volumes within the next two or three years, and will receive the support of all those interested in the subject. This, indeed, he can hardly fail to do, as they will find themselves quite unable to get on without his catalogue when once accustomed to the use of it. The marking of the type of each

genus by an asterisk is an addition of very great value, as compared to the catalogue of Rhopalocera by the same author, and the only serious fault to be found with the book is the upsetting of many well known names by the adoption of Hubnerian genera, and in especial those of the "Tentamen," a mere hand-list of names for that author's private use, and never published or intended to be published, and in accepting which Mr Kirby will find hardly a single lepidopterist to follow him. Hubner's "Verzicknitz" stands on rather different grounds, but even that work is merely a childish collection of names, the species being classified into very heterogeneous groups solely by colour and pattern, and since the divisions which subsequent authors have been pleased to term his genera, though that name might equally well be applied to other of his sections, are neither defined nor the types indicated, it is placed out of Court according to the British Association rules, then again a few well-known generic names, such as *Cossus*, are upset as having previously been used in a specific sense. If these principles were adopted and pushed to their logical conclusion every family of Rhopalocera would have to be re-named and innumerable other changes made, so that nomenclature would be vastly more confusing than it is even now, and the whole subject made unintelligible except to the few who had leisure to make a special study of it. The classification adopted is in the main admirable, the *Castnidae*, however, should perhaps be placed much lower in the scale, the *Uranidae* are rightly disassociated from the *Geometridae*, of which they have hitherto been placed as a sub-family, but a better arrangement would have been to have included in the family the genus *Micromia* and allies, and to have placed it next to the *Epiplemidæ* (*Erosidae* auctorum) and the *Geometridæ*, but these are facts of very recent recognition. The *Aganistidae* again would come better next the *Noctuidæ*, from which they are hardly separable, and the *Syntomidae*, which Mr Kirby calls the *Zygæninae*, are more usually separated from the *Zygænidae*, of which the *Chalosiinae* and *Thymarinae* are considered sub-families. Then again the *Lithosiinae*, *Nyctemerinae* and the *Nyctoolinae* (here called *Cymbidae*) are at most sub-families of the *Arctidae*, and the *Sphingidae*, which are very rightly placed next the *Notodontidae*, should have been preceded by a family composed of the genus *Eupterote* and allies which are still confounded with the *Lasiocampidae*, a family with which they have little or nothing in common. All these, however, are matters of very secondary importance, and the catalogue amply fulfils the one thing required of it that it should be as complete and the references as correct as possible.

G F H

## OUR BOOK SHELF

*Grasses* By C H. Johns, M A 96 pp (S.P.C.K.)

THIS is a separately published appendix to the late Rev C. H. Johns's "Flowers of the Field." In its present handy form it will be acceptable to students who wish to study more minutely our common grasses.

The first three pages are devoted to general remarks on Order Gramineæ. On p 3 a list of the best fodder grasses of Europe is given; *Alopecurus pratensis*, a very valuable and generally useful grass, is omitted, whilst

*Cynosurus cristatus* is included. This latter species is of limited value, and in permanent pasture only.

Genera are given pp. 4-11, and the following fifty pages are occupied by an account of those species which have up to the present been found in Great Britain or Ireland. The rest of the book is devoted to the sedges. The derivations of the names of genera are mostly given, as well as the French and German synonyms of the different species discussed. The illustrations are satisfactory, and are in general given for those species which are most common. That of *Triticum repens*, on p. 32, is perhaps exceptional. The beginner very often confuses the spike of this grass with that of some varieties of rye-grass. The spikelets of the latter are set edgewise to the rachis whilst those of the former have their flat sides to the rachis, if the beginner is still in doubt the rootstock can be examined; this is stoloniferous in the case of couch-grass.

*Elementary Plane Trigonometry* Clarendon Press  
Series By R. C. J. Nixon, M.A. (Clarendon Press, Oxford, 1892)

THE author in his preface informs us that in writing this book he has tried to free his mind as far as possible from all current text-books, and to base this one solely on his experience of twenty-five years. That he has done this is soon seen when glancing through the pages, for the order of arrangement and general basis differ very considerably from those usually adopted. The line of demarcation he draws between elementary and higher works lies in the use and non-use of the symbol  $\sqrt{-1}$ , thus avoiding here altogether the use of imaginaries. An omission which may seem rather questionable is that of the theory of logarithms, which is here excluded as it does not appertain to trigonometry proper; the beginner is not left entirely without logarithms themselves, for there are two chapters in which he can make a slight acquaintance with them, together with one on the adaptation of formulæ to logarithmic calculation. Throughout the work the author has made a strong point of giving in their fulness and generality all definitions and proofs, while he has added also numerous examples, some of which are worked out to serve as specimens, while others are accompanied with hints as to their solution.

If any fault be found in the book it is perhaps that it has been expanded to too great dimensions. Excluding the answers at the end there are no less than 364 pages, which, for an elementary work of this kind, is undoubtedly a large number. At any rate the error is made on the right side. In all other respects the book can be decidedly recommended, for the propositions are all neatly proved, and the get-up, as regards the figures and letters, could scarcely be surpassed.

*Paraguay The Land and the People, Natural Wealth and Commercial Capabilities* By Dr E. de Bourgade La Dardve. English Edition Edited by E. G. Ravenstein. (London George Philip and Son, 1892)

EVERY one who has any reason to be interested in Paraguay ought to read this book, which is in most respects a model of what such a work ought to be. The author spent two years in the country, so that he had ample opportunities for making himself acquainted with its leading characteristics. His impressions, upon the whole, were very favourable, but there is not the faintest attempt to convey an exaggerated idea either of Paraguay's resources or of the use she is making of them. M. de Bourgade writes in a spirit of scientific impartiality, bringing out the facts exactly in accordance with what he believes to be the most trustworthy evidence. He begins with an account of the geographical exploration of the country,

then presents a geological survey, and describes the basins of the Parana and the Paraguay, and Paraguay's vegetable and animal life and minerals. Next there are chapters on various aspects of social life—government, and laws, financial position, real property, population, and immigration. A section on "Labour" includes chapters on means of communication, the soil, stock-breeding, agricultural products, tobacco, timber, textile plants, various raw materials, yerba-maté, and the orange. On all these subjects the author writes clearly and with full information. The work is enriched with a map and illustrations, and of the translation we need only say that it has been done carefully and adequately.

## LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

### Thunderstorms and Sunspots

ABOUT six years ago Prof. von Bezold laid before the Bavarian Academy a memoir relating to lightning-flashes that had done damage to houses in Bavaria. In that kingdom the fire-insurance of buildings is entirely in the hands of the State, and a long series of statistical data on the subject was available.

Two things appeared from this inquiry—first, that those damaging lightning flashes had enormously increased in the last fifty years (to 1882), much more than the increase of houses, and second, that there was apparently some relation between the phenomena and the sunspot cycle. To each maximum of sunspots corresponded a minimum of damaging lightning flashes or thunderstorms (only in two cases one year displaced), but between each pair of minima was another secondary minimum not far from the minimum of sunspots. The curve of lightning damage, in fact, shows a double oscillation for each sunspot period, maxima of sunspots corresponding with the better defined of the two minima of lightning damage. A somewhat similar result had been arrived at by Prof. Fritz from a study of thunderstorms in the Indian Archipelago, but he considered it adverse to the idea of a causal relation between sunspots and thunderstorms.

In an earlier paper to the Bavarian Academy (1874), Prof. von Bezold, from a study of several thunderstorm records, came to the conclusion that "high temperatures and a spotless solar surface give years abounding in thunderstorms." This supposed relation between sunspots and thunderstorms does not seem to have attracted much attention of late years. The object of this note is chiefly to show some curves and figures from thunderstorm records, which, it appears to me, yield further evidence of the relation.

In the diagram herewith are two curves, one for Berlin from 1850, the other for Geneva from 1852. The numbers of days of observed thunder are taken and grouped in averages, each yearly point of the curve representing an average of five years. The vertical scale-figures are to the left. Below is an inverted sunspot curve, with scale-figures to the right. The upper points of the latter are minima, and it will be observed how maxima of the thunderstorm curves occur over them or nearly so, and similarly with sunspot maxima and minima of the other curves. There is not always exact coincidence, but a very considerable correspondence will be noticed. (I do not here reproduce the figures yielding those curves.)

It is to be regretted that the official Greenwich records do not, so far as I know, contain any tabulated series of figures relating to thunderstorms in a long course of years. From an examination of the *Greenwich Observations* and the *Weekly Return*, I am enabled to present a table of the number of days on which thunder was observed during the six months April to September in each year from 1850 to 1891. The actual figures are given in one column, and another column gives smoothed values (five year averages). In the curve made from these smooth values, we find maxima corresponding closely with the sunspot minima of 1856 and 1878, and it is now, apparently, near another pro-

nounced maximum which would correspond with the sunspot minimum of 1889 (I may mention that the number of thunder days this year is, thus far, small, and the smoothed curve seems likely to go down). The sunspot minimum of 1867 seems not to be represented in the curve.

Whether or not we may regard this curve as lending support to the view in question, it may at least prove interesting to observe how our summer thunderstorms have varied in number of late years. The Thunderstorm Committee of the Royal Meteorological Society have not yet, I understand, attacked the question of a possible relation to sunspots. May it not be said, however, that the field looks promising?

While some other Continental records of thunderstorms treated in the same way yield results similar to those for Berlin and Geneva, there are some which cannot be said to support the view under consideration (though also not positively against it). When one reflects on the unsatisfactory nature of many thunderstorm records extending over a long series of years, vitiated by such things as a change of observers, or of the mode of observation or of record, &c., this need hardly be thought surprising.

Year	Greenwich Days Thunder (Apr-Sept)	Smoothed Values	Year	Greenwich Days Thunder (Apr-Sept)	Smoothed Values
1850	8	—	1871	12	10.4

### The Nova Aurigæ.

THE Nova Aurigæ was observed on the night of September 14, with the Newall telescope, under favourable circumstances. It was almost exactly equal in brightness with the star 85"  $\alpha$ , which of the two was brighter it was difficult to say, because of a peculiarity noted below, but its magnitude may be taken as close upon 10.3.

The spectrum, as seen with a compound prism between eye and eye piece, showed a very faint continuous spectrum, varying from C to F (or? G),

a bright line quite, or nearly, coincident with C, three refrangible lines close together in the green, the least refrangible one seeming considerably broader than the others, a faint bright line in the blue (? F),

and with great difficulty I saw at times a still fainter line in the violet. I failed to make out that the bright lines had the dark companions seen in the spring. At first sight the spectrum seemed to consist of a single broad bright line in the green.

With a power of 215 (without spectroscope) I at first thought that the Nova was diffuse, and resembled a minute planetary nebula rather than a star, but on focussing more carefully, I made out that the Nova was distinctly stellar, now, however, the neighbouring stars resembled planetary nebulae. In fact the Nova and neighbouring stars could not be focussed simultaneously. With a power 500 the effect was of course more marked. The Nova owes its visual magnitude nearly entirely to the light that gives rise to the three green lines in the spectrum, and it is interesting to note that it was possible to verify a conclusion drawn from this fact and from the nature of the chromatic dispersion of a refractor of 29 feet focal length—the image of the Nova was distinctly more point-like than that of the neighbouring equally bright star, when each in turn was focussed as carefully as possible. ### Atmospheric Depressions and their Analogy with the Movements of Sunspots

A SOMEWHAT prolonged absence from home has prevented me seeing until now your note on July 21, page 280, in which the writer remarks that the results of M. Camille Flammarion—published in the July number of *L'Astronomie*—"seem to confirm the view suggested by M. Faye that the constitution of [sun] spots resembles somewhat that of the cyclones with which we are familiar."

I write to point out that this is not the theory of M. Faye, but, on the contrary, is the theory of Mr Herbert Spencer, which he published in the *Reader* for February 25, 1865, and which has since been republished in his collected essays under the title, "The Constitution of the Sun." In it Mr Spencer first points out the untenability of M. Faye's hypothesis, and then goes on to say—"The explanation of the solar spots above suggested, which was originally propounded in opposition to that of M. Faye, was eventually adopted by him in place of his own. In the *Comptes Rendus* for 1867, vol. lxxv, p. 404, he refers to the article in the *Reader*, partly reproduced above, and speaks of me as having been replied to in a previous note. Again, in the *Comptes Rendus* for 1872, vol. lxxv, p. 1664, he recognizes the inadequacy of his hypothesis, saying—"Il est certain que l'objection de M. Spencer, reproduit et développée par M. Kirchhoff, est fondée jusqu'à un certain point, l'intérieur des taches, si ce sont des lacunes dans la photosphère, doit être froid relativement. Il est donc impossible qu'elles proviennent d'éruptions ascendantes." He then proceeds to set forth the hypothesis that the spots are caused by the precipitation of vapour in the interiors of cyclones. But though, as above shown, he refers to the objection made in the foregoing essay to his original hypothesis, and recognizes its cogency, he does not say that the hypothesis which he thereupon substitutes is also to be found in the foregoing essay. Nor does he intimate this in the elaborate paper on the subject read before the French Association for the Advancement of Science, and published in the *Revue Scientifique* for March 24, 1883. The result is that the hypothesis is now currently ascribed to him. I should add that, while M. Faye ascribes solar spots to clouds formed within cyclones, we differ concerning the nature of the cloud. I have argued that it is

formed by rarefaction, and consequent refrigeration, of the metallic gases constituting the stratum in which the cyclone exists. He argues that it is formed within the mass of cooled hydrogen drawn from the chromosphere into the vortex of the cyclone. Speaking of the cyclones, he says — "Dans leur combustion évasée ils entraîneront l'hydrogène froid de la chromosphère, produisant partout sur leur trajet vertical un abaissement notable de température et une obscurité relative, due à l'opacité de l'hydrogène froid englouti" (*Revue Scientifique*, March 24, 1883). Considering the intense cold required to reduce hydrogen to the 'critical point,' it is a strong supposition that the motion given to it by fluid friction on entering the vortex of the cyclone, can produce a rotation, rarefaction, and cooling, great enough to produce precipitation in a region so intensely heated" — (*Erays*, 1891 Edition, vol. 1, pp. 188-9).

Churchfield, Edgbaston

F. HOWARD COLLINS

#### Direct Determination of the Gravitational Constant by Means of a Tuning-fork. A Lecture-Experiment

THE following direct experiment for finding the value of the constant  $g$  has proved an instructive one for use with students beginning dynamics, and combines extreme simplicity with greater accuracy than might be anticipated.

A rectangular strip of thick plate-glass with one face lightly smoked is dropped past the end of a sounding tuning fork of known pitch, and which, by means of a light attached style, traces on the smoked surface a fine rippling line whose undulations give a complete record of the relative motion. From measurements of such a trace the value of  $g$  can be determined immediately with an error of not more than  $\frac{1}{2}$  per cent.

For let  $l_1$  and  $l_2$  be the distances fallen through in two equal consecutive intervals of time ( $t$ ). Then  $\frac{l_1}{t}$  and  $\frac{l_2}{t}$  are the velocities at the middles of these two intervals, and  $\frac{l_2 - l_1}{t}$  is therefore the velocity gained in time  $t$ , and  $\frac{l_2 - l_1}{t^2}$  is the acceleration.

With a fork giving 384 complete oscillations per second it was found convenient to take for  $t$  the time of 30 oscillations,  $l_1$  is then the length of any 30 consecutive waves and  $l_2$  that of the next 30. These lengths were measured by means of a millimetre scale printed on card and held against the trace, tenths of a millimetre being estimated. The value of the difference ( $l_2 - l_1$ ) was thus determined from several measures made in different parts of the trace, and, after some preliminary trials, it was found that such measures seldom differed by more than  $\frac{1}{2}$  per cent from their mean, and that the means of different traces agreed about equally well among themselves. Under the given conditions ( $l_2 - l_1$ ) is just under 6 centimetres. The experiment takes only a moment to perform, and the plate can be at once exhibited as a lantern slide.

In order to obtain good traces a little care must be exercised. The smoking should be very light. A fine bristle from a clothes-brush, 2 to 4 cm. long, stuck on with a scrap of wax, may be used as a style, and it should be inclined downwards so as to make an angle of  $45^\circ$  or less with the vertical face of the plate and project well under the plate before this is let fall, so as to be considerably bent while tracing. By furnishing each prong with such a bristle two simultaneous tracings are obtained. Although the method is independent of the actual velocity with which the plate reaches the style, yet it is best to let the plate fall from quite close above the end of the style (within, say, 1 cm.), so that as many wave-lengths as possible may be marked on the plate. The fork also should be strongly bowed with a violin bow, so as to give sharply accentuated ripples, the positions of whose crests are defined with greater precision than would be those of gentler undulations. The plate itself can be conveniently let go if the upper part of its suspension is a single string with a knot at the top, and to prevent its swinging in the air or turning as it descends, it may be held against a narrow smooth backing of hard wood. Without these precautions the trace is liable to show curvature and other irregularities, and indeed under any circumstances the first one or two undulations traced near the advancing edge of the plate are liable to be irregular. The more massive the plate the less is its motion affected by the pressure of the tracing style.

NO 1195, VOL. 46]

Although as a means of finding the value of  $g$  such a method does not compare for accuracy with the use of a pendulum, yet for the converse process of determining the pitch of a fork from measures of its trace and the known value of  $g$ , it may be of utility, for, since the length ( $l_2 - l_1$ ) is proportional to the square of the vibration number, the percentage error will now be halved or reduced to about 1 in 400, and I have little doubt that a careful experimenter, by attending to the causes of error, might further improve on this.

#### A Meteor

ON Wednesday, September 14, at 7h 9m p.m. a large meteor was seen by about twenty people, including myself, who were driving from Penmaenmawr to Conway. It was first observed in the south-east just above the Conway mountain. It was visible for about  $30^\circ$ , fell very slowly in a wavy line inclined at a small angle to the horizon, disappearing behind the mountain. It seemed to be very near the ground as it passed over the mountain.

The sky was quite bright, so that only Mars was clearly visible in it. The meteor appeared to the eye about the size and brightness of Jupiter at the present time, and was of a slightly bluer tint than that planet. There was no perceptible variation in size and brilliance while the meteor was in sight.

GRACE E. CHISHOLM

#### Crater-like Depression in Glaciers.

A PROPOS de la cavité du glacier de Tête Rousse que M. Vallois et moi avons découverte et dont vous parlez dans NATURE (September 1), M. R. von Lendenfeld vous écrit (NATURE, September 15) qu'il a trouvé des dépressions cratériiformes sur le glacier de Lasman, dans la Nouvelle Zélande. Permettez-moi de vous signaler que de pareilles dépressions existent sur certains glaciers des Alpes et notamment sur le glacier de Gorner, ou la carte suisse en indique 26. Elles sont en général à peu près circulaires, leur plus grande dimension horizontale atteint parfois 130 mètres et leur profondeur 30 mètres. L'inclinaison de leurs parois varie en général de  $45^\circ$  à la verticale. Elles reçoivent souvent de l'eau qui s'engouffre au fond dans un moulin ou qui s'écoule, par une crevasse, dans une dépression voisine. Au mois d'août dernier, l'une d'elles formait un véritable petit lac glaciaire que j'ai sondé avec M. Etienne Ritter au moyen d'un bateau démontable, la profondeur de l'eau était presque partout de 5 à 6 mètres, sauf dans un trou, vraisemblablement un moulin, où ma sonde est descendue jusqu'à 21 mètres. Il est probable que, lorsque la pression de l'eau aura élargi le moulin par où elle s'écoule, la cavité se videra.

Les dépressions ne me paraissent avoir aucune analogie avec la cavité que j'ai vue à Tête Rousse. Leur origine est assez mal connue (voir Heim, "Gletscherkunde," p. 246), il est possible, comme le pensait primitivement votre honorable correspondant, qu'elles soient d'anciens moulins transformés.

J'en ai vu une également sur la Mer de Glace, entre le Montanvers et le Tacul.

L'étude de ces dépressions, encore très incomplète, serait très intéressante, et je les signale à l'attention de ceux qui parcourent les glaciers.

Veuillez agréer, monsieur, mes civilités empressées

Thonon, le 17 Septembre

ANDRÉ DELLEBECQUE.

#### GENERALIZATION OF "MERCATOR'S" PROJECTION PERFORMED BY AID OF ELECTRICAL INSTRUMENTS

THE following mode of generalizing Mercator's Projection is merely an illustration of a communication to Section A of the British Association at its recent meeting in Edinburgh, entitled "Reduction of every Problem of Two Freedoms in Conservative Dynamics to the Drawing of Geodetic Lines on a Surface of given Specific Curvature." An abstract of this paper appeared in NATURE for August 18.

In 1568, Gerhard Kræmer, commonly known as "Mercator" (the Latin of his surname), gave to the world

his chart, now of universal use in navigation. In it every island, every bay, every cape, every coast-line, if not extending over more than two or three degrees of longitude, or farther north and south than a distance equal to two or three degrees of longitude, is shown very approximately in its true shape, rigorously so if it extends over distances equal only to an infinitesimal difference of longitude. The angle between any two intersecting lines on the surface of the globe is reproduced rigorously without change in the corresponding angle on the chart.

Mercator's chart may be imagined as being made by coating the whole surface of a globe with a thin inextensible sheet of matter—sheet india-rubber for example (for simplicity, however, imagined to be perfectly extensible but inelastic)—cutting away two polar circles to be omitted from the chart, cutting the sheet through along a meridian, that of  $180^\circ$  longitude from Greenwich for example, stretching the sheet everywhere except along the equator so as to make all the circles of latitude equal in length to the circumference of the equator, and stretching the sheet in the direction of the meridian in the same ratio as the ratio in which the circles of latitude are stretched, while keeping at right angles the intersections between the meridians and the parallels. The sheet thus altered may be laid out flat or rolled up, as a paper chart.

What I call a generalized Mercator's chart for a body of any shape spherical or non-spherical, is a flat sheet showing for any intersecting lines that can be drawn on a part of the surface of the body, corresponding lines which intersect at the same angles. One Mercator chart of finite dimensions can only represent a part of the complete surface of a finite body, if the body be simply continuous; that is to say, if it has no hole or tunnel through it. The whole surface of an anchor ring can obviously be mercatorized on one chart. It is easily seen, for the case of the globe, that two charts suffice to mercatorize the whole surface, and it will be proved presently that three charts suffice for any simply continuous closed surface, however extremely it may deviate from the spherical form.

In "Liouville's Journal" for 1847, its editor, Liouville, gave an analytical investigation, according to which, if the equation of any surface whatever is given, a set of lines drawn on it can be found to fulfil the condition that the surface can be divided into infinitesimal squares by these lines and the set of lines on the surface which cut them at right angles. Now it is clear that if we have any portion of a curved surface thus divided into infinitesimal square allotments, that is to say, divided into infinitesimal squares, with the corners of four squares together, all through it, we can alter all these squares to one size and lay them down on a flat surface with each in contact with its four original neighbours; and thus the supposed portion of surface is mercatorized. Except for the case of a figure of revolution, or an ellipsoid, or virtually equivalent cases, Liouville's differential equations are of a very intractable kind. I have only recently noticed that we can solve the problem graphically (with any accuracy desired if the problem were a practical problem, which it is not) by aid of a voltmeter and a voltaic battery, or other means of producing electric currents, as follows—

1 Construct the surface to be mercatorized in thin sheet metal of uniform thickness throughout. By thin I mean that the thickness is to be a small fraction of the smallest radius of curvature of any part of the surface.

2 Choose any two points of the surface, N, S, and apply the electrodes of a battery to it at these points.

3 By aid of movable electrodes of the voltmeter, trace an equipotential line, E, as close as may be around one electrode, and another equipotential line, F, as near as may be around the other electrode. Between these two equipotentials, E, F, trace a large number,  $n$ , of equi-

different equipotentials. Divide any one of the equipotentials into  $n$  equal parts, and through the divisional points draw lines cutting the whole series of equipotentials at right angles. These transverse lines and the equipotentials divide the whole surface between E and F into infinitesimal squares (Maxwell, "Electricity and Magnetism," § 651).

4 Alter all the squares to one size and place them together, as explained above. Thus we have a Mercator chart of the whole surface between E and F.

N and S of our generalization correspond to the north and south poles of Mercator's chart of the world, and our generalized rule shows that a chart fulfilling the essential principle of similarity realized by Mercator may be constructed for a spherical surface by choosing for N, S any two points not necessarily the poles at the extremities of a diameter. If the points N, S are infinitely near one another, the resulting Mercator chart for the case of a spherical surface, is the stereographic projection of the surface on the tangent plane at the opposite end of the diameter through the point, C, midway between N and S. In this case the equipotentials and the streamlines are circles on the spherical surface cutting N S at right angles, and touching it, respectively.

For a spherical or any other surface we may mercatorize any rectangular portion of it, A B C D, bounded by four curves, AB, BC, CD, DA, cutting one another at right angles as follows. Cut this part out of the complete metallic sheet, to two of its opposite edges, A B, D C, for instance, fix infinitely conductive borders. Apply the electrodes of a voltaic battery to these borders, and trace  $n$  equidifferent equipotential lines between AB and DC. Divide any one of these equipotentials into  $n$  equal parts, and through the divisional points draw curves cutting perpendicularly the whole series of equipotentials. These curves and the equipotentials divide the whole area into infinitesimal squares. Equalize the squares and lay them together on the flat as above.

If we have no mathematical instruments by which we can draw a system of curves at right angles to a system already drawn, we may dispense with mathematical instruments altogether, and complete the problem of dividing into squares by electrical instruments as follows. Remove the conducting borders from AB, DC, apply infinitely conductive borders to AD and BC, apply electrodes to these conducting borders, and as before draw  $n$  equidifferent equipotentials. This second set of equipotentials, and the first set, divide the whole area into squares.

KELVIN

#### THE ACTIVE ALBUMEN IN PLANTS<sup>1</sup>

ONE of the most important chemical functions of plant-cells is that synthesis of albuminous matter which serves for the formation of protoplasm. The *living* protoplasm, however, is composed of proteids entirely different from the ordinary soluble proteids, as well as from the proteids of *dead* protoplasm. In other words, if living protoplasm dies, the albuminous constituents change their chemical character. We observe that in the living state a faculty of autoxidation (respiration) exists, which is wanting in the dead condition; and Pflüger, in 1875, drew from this the conclusion that in protoplasm the chemical constitution of the living proteids changes at the moment of death.

Various other considerations force us to accept this logical conclusion. Chemical changes readily occur in all those organic compounds that are of a *labile* character. There exist so-called labile atom constellations that are in lively motion, and are thus prone to undergo change, the atoms falling into new arrangements which

<sup>1</sup> This paper was read before the Libys meeting of the International Congress of Physiologists, of whose proceedings we gave some account last week.

present more stable constellations<sup>1</sup>. We do not doubt that *vital force is a mode of motion* due to the presence of atoms in labile positions in the albuminous substance. The motion ceases when there occurs a migration of the labile atoms to some stable position. The aldehydes give us fine illustrations of labile combinations and stable rearrangements in other allied substances.

The question now arises, can we chemically demonstrate that the albuminous substance formed by synthesis in plants is—even before it has become protoplasm—different from ordinary albumen? It was known long ago that the juice of plants—that is the aqueous solution in the vacuoles of the cells—contains albumen, but it was thought to be ordinary albumen. It is easy to prove that this is not the case<sup>2</sup>.

On treating living plant cells with dilute solutions of ammonia or organic bases or their salts, remarkable changes are observed. These consist either in the formation of numerous minute granules as is the case on the application of most of the bases, or in the production of little globules flowing together to make relatively large drops of a substance of high refractory power, as is the case on the application of weak bases like caffeine or antipyrin<sup>3</sup>. These latter two bases in weak solution do not injuriously affect the protoplasm itself, since the cells will keep alive for a number of days in a 0.5 per cent solution of these bases, the cells are, however, soon killed by other bases and their salts. The granules and globules formed in the living cells by the action of caffeine have been called by Bokorny and myself *Proteosomes*. They give the principal reactions of albuminous bodies, but contain in most cases an admixture of small quantities of lecithin and tannin. These admixtures, however, can be removed by cultivating the objects (the alga, *Spirogyra*, for instance) in solutions rich in nitrates. If now by such cultivation the tannin has been removed and the proteosomes then produced by treatment with caffeine, we can observe that these albuminous proteosomes are capable of reducing silver from even highly diluted alkaline solutions. This property is lost after treatment with dilute acids as well as after the death of the cells<sup>4</sup>. In these cases the proteosomes become hollow and turbid, their substance appearing to coagulate and shrink.

There are thus experimental grounds for the conclusion that not only the organized albumen of the living protoplasm, but also the albumen dissolved in the vacuoles—the unorganized albumen—is a different substance from the ordinary albumen, which is present in dead cells. We may sum up the line of argument as follows—

I. Bases act upon the albumen of living cells, not, however, upon that of dead cells, nor upon ordinary dissolved albumen.

II. The action may be observed microscopically to take place in the case of various vegetable objects in the liquid portion of the protoplasm itself as well as in the vacuoles. This can be specially well observed with the alga *Spirogyra* when treated with caffeine.

III. The granules and globules into which the active albumen aggregates by the action of bases—called by us proteosomes—have the property of reducing dilute silver solutions in the absence of light, and lose this property by the action of acids.

IV. The active albumen in its most *unchanged* condition can be made visible by caffeine or antipyrin, two bases that do not act as serious poisons to the cells. Living cells containing proteosomes, brought out by caffeine

when placed in distilled water regain their original condition, the proteosomes become gradually dissolved again (rapidly at 25° C.), and a new application of caffeine will now make them reappear.

V. If proteosomes are produced by caffeine or antipyrin, and the death of the cells is then caused by ether vapour, &c., it may be easily observed that soon after the death of the protoplasm the proteosomes of the vacuoles are also changed in their optical and chemical properties, they become turbid and hollow, they coagulate, and they lose their property of being resolvable in distilled water.

O. LOEW

#### DISCOVERY OF A FIFTH SATELLITE TO JUPITER

IN January of the year 1610 Galileo, at Padua, in Italy, discovered four satellites revolving round Jupiter, and though more than 282 years elapsed in the interval, from that time to August, 1892, no additional satellites were detected near this planet, and astronomers naturally inferred that no others existed. The fact that Jupiter possessed four satellites has become familiar to every schoolboy, for it has been repeated in all the astronomical text-books published during nearly three centuries. Few people therefore could have imagined that the statement would ever be controverted or rendered untenable by new discoveries. In regard to the more distant planets Uranus and Neptune, there was every prospect of additional satellites being detected, but with Jupiter the circumstances were somewhat different. The four satellites were so bright and so palpably visible in very small telescopes that it was scarcely thought possible that another existed small enough to remain unseen. Moreover, there was a significant agreement in the relatively increasing numbers of the satellites surrounding the planets Mars, Jupiter, and Saturn. Mars was known to have two satellites, Jupiter four, and Saturn eight, the number doubling itself with each step outward from the sun, and it was considered probable that the harmony of the series would not be disturbed.

Now, however, the astronomical world has been excited by the announcement that a new satellite has been discovered in attendance on Jupiter, and that its distance from the centre of the planet is 112,400 miles, and its period of revolution 17 hours 36 minutes. The discovery was effected by Prof. Barnard, of the Lick Observatory on Mount Hamilton in California, and, as he has already proved himself a very acute observer, especially of comets, and as he has the occasional use of what is supposed to be the most powerful telescope hitherto constructed, there is no good reason to discredit the intelligence.

People will be obviously led to ask how this new satellite managed to evade detection during nearly three centuries of diligent telescopic research. How was it that one at least of the host of observers who have studied this plane and his circling moons by means of powerful glasses, did not sight the tiny orb which has now revealed itself to the watchful American astronomer? We imagine that the chief reason for this want of success is to be found in the fact that the new orb is not brighter than the thirteenth magnitude, and that, being situated close to its primary, it would therefore, in ordinary instruments, be quite obliterated in the surrounding glare. But it is perhaps rather singular that it was not detected by its shadow, which would be projected on the disc of Jupiter whenever the satellite passed between the planet and the earth, and this would be of daily occurrence. At such a time the shadow would appear as a small, black, circular spot moving rapidly from east to west across the disc, and with greater apparent velocity than the visible

<sup>1</sup> Many examples can be cited from organic chemistry; for instance, the rapid change of the diamidoacetone as soon as it is liberated from its salts (Berichte d. Deutschen Chem. Ges., 25, 1563). Compare also the article,

<sup>2</sup> "Chemical Motions," Biolog. Centralblatt ix. N. 16.

<sup>3</sup> O. Loew und Th. Bokorny, Biolog. Centralblatt xi. 1.

<sup>4</sup> These globules closely resemble the aggregated masses that Darwin observed after irritation of leaves of *Drosera*.

<sup>5</sup> The proteosomes produced by ammonia and various other bases preserve this property for a much longer time after the death of the cell than those produced by caffeine or antipyrin.

markings. And it is quite possible that the shadow has been observed on more than one occasion, but mistaken for an ordinary spot on the surface of Jupiter.

A curious fact in connection with the new satellite is its diminutive size as compared with the four others discovered by Galileo in 1610. But there is a similar disparity in the dimensions of the satellites of Saturn, and in proof of this we have only to compare the bright *Titan* with the excessively faint *Mimas* and *Hyperion*. Small as it is, however, it is certain that this new satellite of Jupiter is much larger than either of the two abnormally minute moons of Mars.

American astronomers are to be congratulated on this important discovery. Scientific activity in the United States has been rapidly developing in recent years, and this has been strikingly exemplified in the wide and attractive domain of astronomy. W. F. DENNING.

### NOTES

THE French Association for the Advancement of Science is holding at Pau its twenty-first annual meeting. The meeting began on Saturday last, when the members of the Association were cordially welcomed to Pau by the Mayor. The President, M. Collignon, delivered an address on the science and art of the engineer.

THE autumn meetings of the Iron and Steel Institute, under the presidency of Sir Frederick Abel, began at St. George's Hall, Liverpool, on Tuesday. At the opening meeting the President announced that the Council had elected Mr. Windsor Richards as his successor.

WE are glad to announce that a new Biological Laboratory is about to be established in the Calcutta Zoological Gardens. Babu Joy Gobinda Law, a member of one of the wealthy native families of Bengal, has offered Rs. 15,000 for the buildings and fittings of this institution. The primary object for which the Laboratory is founded is to investigate the action of snake-poison, and to discover, if possible, an antidote. The Laboratory will, however, also be used for anatomical and pathological researches, for which the rich material afforded by the animals in the gardens will be available.

THE Marine Biological Laboratory at Wood Hole, U.S., has been more successful this summer than in any previous year. During its season of work it had a corps of seventeen officers, instructors, and assistants, and an attendance of thirty-eight investigators and sixty-two elementary students.

WITH the designation of the Hopkins Seaside Laboratory, a marine biological laboratory has been established at Pacific Grove, California. We learn from the *Botanical Gazette* that, through the generosity of the Pacific Improvement Company, a piece of land has been furnished, and a sum granted sufficient to erect a plain frame building, and, by the liberality of Mr. Timothy Hopkins, provision is made for the equipment of the building, and for the further continuation and extension of the enterprise. An elementary course of lectures on marine botany was to be given during the present season.

THE weather during the past week was very fine and bright over the southern and eastern portions of the United Kingdom, until near the close of the period, when the type entirely changed, and thunderstorms, accompanied by heavy rain, occurred generally, but in the north and west the conditions were throughout far less settled. Cyclonic disturbances arrived on our coasts from the Atlantic with considerable frequency, and although they were for the most part slight and shallow, and unaccompanied by much wind, they were productive of a considerable quantity of rain. An important disturbance passed to the north of Scotland on

Thursday night and during Friday, and was accompanied by strong gales on our north-west and north coasts. Temperatures were high for the season over the greater part of England, and on Monday the day readings in places were higher than at any time during the month, the shade thermometer registering  $72^{\circ}$  in London. Some nights, however, were exceptionally cold, the shade minimum between Saturday and Sunday falling to within one degree of the freezing point in the eastern part of England, while there was a sharp frost on the ground open to the sky. The *Weekly Weather Report*, issued on the 17th inst., shows that the rainfall exceeded the mean in the north and west of Scotland and in the north of Ireland. In all the other parts of the United Kingdom there was a deficit, in most of the English districts the fall was very slight.

THE Report of the Meteorological Commission for the year 1891 states that complete, or nearly complete, meteorological observations have been received from forty-nine stations, and that observations of rainfall have been furnished from 320 stations, the instruments are usually supplied by the Commission. The Report contains diagrams showing the mean monthly rainfall corrected to date at thirty-three stations, together with the abnormal falls in the years 1888 and 1891. The rainfall in 1891 has been excessive, especially over the eastern part of the colony and over the Orange Free State, where at some places it exceeded 12 inches above the average. The observer at Philippolis states that hardly a farmer in that district but has lost one-third of his sheep, owing to the continued wet, and in some places the farmers have had to vacate their homes in consequence of the weather.

THE "Pilot Chart of the North Atlantic Ocean" for September contains tracks of the drift of the two parts of the derelict ship *Fred B. Taylor*, which was cut in two by a collision on June 22, in lat  $40^{\circ} 19' N$ , long  $68^{\circ} 33' W$ . The forward and after parts separated, and drifted in entirely different directions, in a manner which is quite unprecedented in the history of shipwrecks. The after end was evidently influenced more by wind than the bow portion, the latter pursued a south westerly course, which was attributable largely to the cold southerly current between the American coast and the Gulf Stream, and on August 26 had drifted to lat  $38^{\circ} 40'$ , long  $73^{\circ} 15'$ . The stern part took a direct northerly course until July 17, when it was ten miles north west of Matinicus Island, whence it took a westerly course, and was cast ashore on August 7 on Wells Beach, near Cape Porpoise.

THE first annual convention of the American Association of State Weather Services was held at Rochester, N.Y., on August 15 and 16, in conjunction with the meeting of the American Association for the Advancement of Science, and was largely attended by representatives of the various States. The subject of thermometer exposure was discussed, and a committee was appointed to consider the most suitable form of shelter and manner of exposure to be adopted throughout the country. It was resolved that means should be deduced from self-registering instruments wherever practicable, in preference to the method of using eye observations. An interesting paper was read by W. L. Moore, of Wisconsin, on the forecasting of thunderstorms, and the question of the best methods of signaling weather forecasts, whether by flags, semaphores, spherical bodies hoisted on a staff, &c., was freely discussed, and a committee was appointed to report upon the subject at an early date. It was decided that each State service should have a separate exhibit at the World's Fair at Chicago, and not to have the exhibits collected in the building for the use of the United States Weather Bureau.

LAST year an Aino in the western part of the island of Yezo caught two bears, one of which was perfectly white. This

capture created much excitement among the natives, as their chief god is a white bear, and he is supposed to dwell on an inaccessible mountain in the interior of the island, and never to let himself be seen by human beings. The Ainos, therefore, concluded that the young white bear was a sort of Messiah, and after long consideration they decided that he ought to be sent as a present to the Mikado. In due time he arrived at Tokio, and by the Mikado's orders he was received into the Zoological Garden. Here the animal soon became ill, and Herr J. L. Janson was requested to do what he could for it. Fortunately his treatment of it was successful. At first he thought the creature must be a polar bear, but he soon convinced himself that this was a mistake, and that it was in reality an albino. In the latest number of the "Mittheilungen der Deutschen Gesellschaft für Natur- und Völkerkunde Ostasiens in Tokio," Herr Janson gives a full account of the bear, and he adds some interesting facts as to the importance attributed to white animals generally, and especially to albinos, in Japan. The appearance of an albino is supposed to be a good omen for the reigning monarch. The reign of a sovereign may even be known by the name of a white animal. Thus the reign of one ancient Mikado is called "Hakuchi nenkan," the period of the white pheasant. That of another is "Haku hō nenkan," the period of the white phoenix. The white fox is often mentioned in fables and temple-stories, and a white serpent always appears in pictures and plastic representations with Benten, the goddess of fortune. As in former times among the Greeks, Romans, Persians, and Scythians, so among the Japanese, horses dedicated to the gods were generally white, and white horses are still found in connection with all the larger temples, and take part in the great annual processions. The milk and butter derived from white cows were formerly held in high esteem as medicine.

MR. F. W. WARD, formerly editor of the *Sydney Daily Telegraph*, has sent to the Agricultural Department of New South Wales a report on recent shipments of fruit from Cape Colony to London. The report is printed in the July number of the *Agricultural Gazette of New South Wales*, which recommends it as "worthy of careful perusal." The *Gazette* refers to the fact that good fruit growing districts abound in Australia, and that no better fruit can be grown in South Africa than is now being produced in many districts of New South Wales. The chief mistake hitherto, it says, has been the growing of unsuitable varieties—unsuitable not alone for export, but even for ordinary home use. It adds that this defect is being rapidly remedied, and that many growers, who have gained experience by their own efforts, are settling down to the work with intelligent earnestness.

WRITING of wild strawberries in Ceylon, Mr. Nock says in the *Ceylon Observer* that the species *Fragaria vesca*, which grows so luxuriantly and fruits so abundantly in Jamaica, is now growing wild in many places in the Nuwara Eliya district. If the soil in Ceylon were as good as it is in the Blue Mountains of Jamaica, and there was less Nilu (*Strobilanthes*), this strawberry would soon, he thinks, be as plentiful in the hill districts of Ceylon as it is there. When Mr. Nock was Superintendent of the Government Cinchona Plantation in Jamaica, he has given as many as twenty free tickets in one day to old women and children to gather strawberries among the Cinchona Plantations. He has known them gathered by the bushel, and carried twenty-two miles to the Kingston market, where they always commanded a good price. He adds that he has this year raised seedlings of six of the best English varieties, to which he intends to give a fair trial in the Nuwara Eliya district.

THE University of Minnesota has begun the publication of a *Quarterly Bulletin*, under the management of a board of editors.

The chief editor being Prof. Conway M'Millan, the professor of botany to the University, is a guarantee that the interests of science will not be neglected in the *Bulletin*, and the first number contains several items of information of interest to American botanists.

IN the report of the Royal Botanic Garden, Calcutta, for the year 1891-92, it is shown that the year was one of great activity as regards outdoor operations. The abnormally dry season proved very trying to many exotics, and, though for a time all other work was suspended and the whole garden staff was employed only in watering plants, many casualties occurred, especially among the finer and rarer plants. The attention of the staff was as usual largely directed to the cultivation and distribution of plants of economic interest. The chief event of the year under this head was the introduction of the aloe, which yields "sisal hemp" (*Agave rigida*, var. *sisalana*). The Director of the Royal Gardens, Kew, in June 1891, kindly obtained a consignment of plants for the Calcutta Garden from Florida, and kept these at Kew till they were strong enough to stand the voyage to Calcutta. The boxes reached Calcutta on October 29, 1891, unfortunately a considerable percentage of the plants died on the way out, and it was necessary to nurse the survivors carefully before they could be distributed. Over 19,000 specimens were contributed to the Herbarium during the year from various sources, while the distribution of authentically-named specimens to other herbaria reached the high total of 10,505 sheets. The chief benefactor to the Calcutta Herbarium was again the Royal Herbarium, Kew, to the Director of which institution the Calcutta one "owes a debt that can never be repaid." Among other contributors was Baron von Mueller, who again sent a beautiful collection of Australian plants. The Herbarium was also greatly enriched by further accessions of Tibetan, Chinese, and Mexican specimens, and the Saharanpur Herbarium presented 954 plants from the north west Himalaya. Dr. Prain visited the Andaman Islands, Mount Parashak, and the Khasia, and was thus enabled to add valuable collections. Much good work was also done by collectors employed by the Calcutta Garden.

IN the second number of the *Journal of the Polynesian Society* Dr. A. Carroll, of Sydney, offers what he believes to be translations of some of the famous Easter Island inscriptions. He is of opinion that Easter Island was at one time occupied by a pre Polynesian people from America, and that to them the inscriptions are to be attributed. "While engaged in studying the languages, histories, antiquities, and inscriptions of ancient American peoples," he says, "I came upon similarities to the Easter Island characters, &c., with these as keys, discovered what certain groups expressed, and from these, proceeding upon the recognized methods of decipherment, succeeded in reading into the original languages, and from these translating into English these Easter Island inscriptions." This is very vague, and, until Dr. Carroll gives some more definite information as to his methods, his claim that "another ancient writing is deciphered" will seem somewhat extravagant. Among the other contents of the number are an interesting account of some stone implements from the Chatham Islands, by Mr. S. Percy Smith, and the first part of a history of the occupation of the Chatham Islands by the Maoris in 1835, by Mr. A. Shand. Mr. Shand's information has been derived from the Maoris themselves, many of those who supplied it having taken part in the transactions they described.

MR. WILLIAM KENT, writing in *Science* on the American Association for the Advancement of Science, complains that it does not adequately represent the scientific movement in the United States. He points out that while more than 2000 members attended the Edinburgh meeting of the British Association,

there were not 500 members at the Rochester meeting of the American Association, and of this number New York State contributed far more than its quota. In proportion to its population, Ohio sent twice as many members as Pennsylvania, although its average distance from Rochester is greater. Moreover, the several branches of science are not equally represented. Mechanical and engineering science, which is developing in the country by leaps and bounds, sends to the Association only one fourth as many members as chemistry, and one-eighth as many as biology. The physical sciences, Mr Kent says, are "dwarfed by the natural sciences." This he attributes to the fact that those who devote themselves to applied science have so many societies of their own that they are diverted from and lose their interest in the American Association. In engineering there are four large national societies, the civil, the mechanical, the mining, and the electrical, besides numerous local societies, aggregating a membership of probably 5000 persons, not counting duplications of those who belong to two or more societies.

A MOVEMENT has been started in Melbourne for the passing of a law which may tend to prevent the wanton destruction of birds in Victoria. A deputation, organized by the Victoria Field Naturalists' Club and representing the Melbourne Royal Society, Royal Agricultural Society, Royal Horticultural Society, and Zoological and Acclimatization Society lately brought the subject under the notice of the Minister of Customs. In introducing the deputation, Messrs G D Carter and J Bosisto dwelt upon the necessity of protecting insectivorous birds from the reckless and indiscriminate shooting which is now so prevalent, as well as human lives, which are frequently sacrificed to the inexperience of sportsmen. The imposition of a gun tax as a legitimate source of revenue was also suggested. Prof Kernot (Royal Society), Mr. C M Officer (Zoological Society), and Mr C Draper (Royal Agricultural Society) also emphasized these views. Mr F Wisewould referred to the draft which had been drawn up by the sub-committee of the Field Naturalists' Club—a draft based upon similar Acts in England and some of the Australian colonies. A few new features had, however, been added, notably that which made it illegal for persons under the influence of liquor to carry firearms. It was also provided that under no circumstances should a licence be given for the use of swivel guns. In answer to the deputation the Minister said that he would take the draft bill which had been prepared into favourable consideration. He would have an amended draft drawn up and submitted to those interested before its introduction into Parliament. He was of opinion that a 5s tax, as proposed, was not heavy enough, since it would be worth the while of those who let out guns to pay the tax themselves.

THE serum of blood used to be regarded as merely a nutritive liquid, but it has been found to play a more important part, being capable of killing disease germs, and of destroying and dissolving the red blood corpuscles of other animals. These properties have been recently studied by Herr Buchner (*Münchener Med. Wochenschrift*). They are gradually lost when the liquid has been removed from the animal. They are also destroyed by heating half-an-hour to 52° to 55° C. (A dog's serum stops the amoeba-like movements of white-corpuscles of another animal species without killing them, but this property is also lost by heating to 55°). Light also stops both actions, and diffuse daylight more than direct sunlight. It is apparently albumens in the serum that are operative, but whether all the albuminoid constituents, or certain specific albumens, was not determined. It is remarkable that solution of the serum with a 0.7 per cent solution of common salt does not spoil the action, whereas a similar dilution with pure water makes the serum nearly inactive. But serum thus made inactive with water re-

covers its properties if salt solution is added, and this is the case even when the serum has been kept in the active state for four to 24 hours in ice. Serum may also receive a 0.7 per cent solution of potassium or lithium chloride, or various other salts of the fixed alkalis, without losing its germicide properties. Ammonium salts even stimulate the latter. Herr Buchner calls the albumens in question alexines (or protective matters), he supposes they have a like action on foreign cells generally. The serum of dogs and rabbits having been mixed, the power of both alexines was weakened, but those of the rabbit more than those of the dog (to typhus bacilli). After acting some time on each other the globulicide power was quite extinguished. The author finds in these facts an explanation of the antitoxical action of the serum of animals protected against disease.

ACCORDING to the *Revista Financiera Mexicana*, quoted in the current number of the *Board of Trade Journal*, a deposit of onyx of considerable importance has just been discovered in Mexico, about 50 kilometres south of El Paso. It is said to be of superior quality, with fine grain, and richly shaded with delicate and varied tints. Blocks of considerable dimensions can be easily extracted.

DR MORRIS GIBBS writes to *Science* from Kalamazoo, Michigan, that in that State there are to his knowledge six species of birds which feed on acorns. Of these, the passenger-pigeon and mourning-dove swallow the acorn entire, with its shell intact, only removing the cup or rough outside covering. The white-bellied nut-hatch occasionally hoards the acorns away, and only draws on its store after some months, and when the firm shelly covering readily gives way to its sharp, prying bill. The other three are the well-known blue jay, common crow-blackbird, and red headed woodpecker. So far as he has been able to learn, these birds, except in rare instances, do not pick the acorns from the tree, but have to content themselves with the fallen fruit. The red head, deigning to descend to the ground, seizes an acorn, and flying with it in its bill to a spot where there is a small cavity in the dead portion of a trunk, or to a crevice in the bark, immediately begins to hammer it with its sharp-pointed bill. In a couple of strokes, it has removed the outer shell or cup, and at once attacks the still green-coloured shell which directly surrounds the meat. The inside, or shell proper, quickly gives way, usually nearly in halves, and the woodpecker enjoys the kernel. The woodpeckers are as nearly strict insect-feeders as any birds in Michigan, unless an exception is made of the swifts and swallows, yet here is an instance of a varied diet. However, the red-head is quickly satisfied in the acorn line, and soon begins circling the trunk, or more often limbs, for his legitimate food. The blackbird confines himself to the ground in his efforts for acorn meats. Walking up sedately to an acorn, and making no effort to seize or confine it, it strikes savagely and almost aimlessly. Its bill frequently glances, and the splintered shell dances about, until at last a huge piece of the kernel is dragged out, after which the bird leaves for other quarters or begins on another acorn. The jay swoops down with flaunting blue wings, and, seizing the largest acorn on the ground, flies to the nearest convenient limb or to the decayed ridge-board of an adjacent building. There, firmly pressing the nut between his big, black feet, he hammers away with a vengeance, and quickly tears off nearly half of the shell, after which he proceeds to pick out the meat in small bits. The cup is often left nearly perfect, the jay never making an effort to secure the nut entire, which he could easily do. Walking under the oaks, one can readily tell whether the woodpeckers, blackbirds, or jays have been at work among the acorns, by the appearance of the mutilated shell-remains lying about.

THE following arrangements have been made for science lectures at the Royal Victoria Hall during October —October 4, Sir John Lubbock on "Books" After the address he will present the prizes and certificates gained by students of the M M College, Prof. Foxwell in the chair October 11, Mr C T Dent (late President of the Alpine Club), on "The Alps in Winter" October 18, Mr F W Rudler, on "Frost and Fire," with special reference to the flood at St Gervais, and the eruption of Etna October 25, Col Swinhoe on "Some Curiosities in Nature"

LAST week we noted that Messrs Macmillan and Co had issued a new edition of "Arithmetic for Schools" This is the well-known work by Mr Barnard Smith The book has been revised and enlarged by Prof W H H Hudson

MESSRS GAUTHIER-VILLARS have issued "Bulles de Savon," a translation, by C L Guillaume, of Mr Boys' little work on "Soap Bubbles" The translator, while reproducing the main features of the book, has, with the author's sanction, adapted it for the use of French readers He has also incorporated an account of some new experiments which Mr Boys has brought to his notice

THE first number of a new German journal, which promises to be of considerable interest to non professional students of science, has just been issued in Berlin, the publisher being R Oppenheim It is entitled *Natur und Haus*, and is edited by L Staby and M Hesdorffer The articles are written in a popular style, and well illustrated

THE additions to the Zoological Society's Gardens, during the past week include a Mona Monkey (*Cercopithecus mona* ♀) from West Africa, presented by Col Makins, a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mrs Palmer, a Vulpine Squirrel (*Sciurus vulpina* ♂) from North America, presented by the Hon G Carew, a Malayan Tapir (*Tapirus indicus* ♂) from Malacca, presented by Col J M Jenkins, a Great Eagle Owl (*Bubo maximus*), European, presented by Commander Ernest Rason, R N, a Black-crested Cardinal (*Gubernatrix cristatella*) from South America, presented by the Rev W B K Frances, a Small Hill Mynah (*Gracula religiosa*) from India, presented by Mr George Grigs, a Long-nosed Crocodile (*Crocodilus cataphractus*) from the River Juba, East Africa, presented by Capt. F G Dunbar, R N, two —Tortoises (*Testudo* —), five Cinxys (*Cinxys* —), a Puff Adder (*Vipera asietans*) from East Africa, presented by Mr D Wilson, a Pig-tailed Monkey (*Macacus nemestrinus* ♂) from Java, a White-backed Piping Crow (*Gymnorhina leucotis*) from Australia, an Adorned Terrapin (*Clemmys ornata*) from North America, a Kobben Island Snake (*Coronella phocarium*) from South Africa, deposited, a Red Kangaroo (*Macropus rufus* ♀), a Black-fronted Weaver Bird (*Hypotrionchus velatus*) bred in the gardens

### OUR ASTRONOMICAL COLUMN

PROPOSED SCHOOL OF PRACTICAL ASTRONOMY —Mr H C Russell, Government Astronomer of New South Wales, in a paper read before the Royal Society of Tasmania, makes some very practicable, and what we think excellent, suggestions with respect to the disposal of the sum of money (£10,000) left by the late Mr Leake for the foundation of a school of astronomy The idea is for the Leake trustees to co operate with the University of Tasmania, and in this way form a complete school in which both the theory and practice of astronomy should be dealt with simultaneously In addition to the observatory being merely a school for students, Mr Russell suggests that it should take up some special line of research, and proposes that of astronomical photography This seems an excellent proposition The work which such an observatory as this could do if thoroughly equipped with the necessary apparatus, would be very considerable, and the special advantages of climate and position, to say nothing of the unexplored state of the

southern heavens, would soon render it of great importance There is no doubt that we are not yet overburdened with a surplus of observatories in the southern hemisphere, for even now there is a doubt as to how the international photographic chart of the heavens shall be provided for in this region, three observatories which have undertaken the work having been unable to carry out their plans on account of the political troubles Should this proposal be accepted, the new Leake Observatory will start under good auspices, as it will fill up a gap by taking in hand a share of the greatest modern astronomical enterprise

DOUBLE STAR MEASURES —Mr S W Burnham, in *Astronomische Nachrichten*, Nos 3113-14, gives a list of all the double star measures that he has made during the year 1891 with the 36-inch of the Lick Observatory Most of the stars here included may be classed as difficult objects, being too close for any smaller aperture, and all of them more or less unequal As Mr Burnham tells us, many of the stars are taken from his own catalogues, it being rather important to measure them at this time, since several are in very rapid motion Owing to the fact that some of these stars have not been measured since the time of their discovery, it is interesting to note the changes that have taken place Observations of these have "shown some very remarkable changes, and have shown the existence of some of the most remarkable binary systems known" Measurements have also been made of some of the closest and most difficult binaries from the discoveries of Clark, Struve, and others The epoch for the star places is as heretofore 1880

COMET BROOKS (1882, AUGUST 27) —From *Edinburgh Circular*, No 31, we make the following extract of the elements and ephemeris relating to the comet discovered by Mr Brooks at Geneva on the 27th The computations are based on four observations made between August 31 and September 5 —

#### Elements

T = 1892 Dec 19 727 M T Berlin

The brightness at the time of discovery is taken, as usual, as the unit of Br

NOVA AURIGÆ —Some short notes with regard to Nova Aurigæ are communicated to *Astronomische Nachrichten*, No 3114, which may be of interest here —On Sept 3, Dr F. Ristenpart, of the Observatory in Karlsruhe, with a 6 inch refractor, by comparing the Nova with the brightness of an accompanying star, estimates the Nova as of the 9.65 magnitude of the Bonn scale. Herr Cand. F. Kroeger observed the Nova on three different occasions —Sept 3, 4, and 6 Comparing it with a neighbouring star of the 9.5m (Star—Nova = + 3s 5 + 1' 2), the Nova was found to be about "a degree dimmer than the comparison star" On Sept 4 the seeing was much better, and the Nova was about "two degrees brighter than the comparison star" On the third occasion, with excellent definition, the comparison star and the Nova were of equal brightness. These observations are all made between 12h. and 12h. 30m. Kiel mean time. Prof E E Barnard has also made a very interesting observation with the 36 inch of the Lick Observatory, finding that the Nova appeared as a small, bright nebula, with a star like nucleus of the 10th magnitude The nebulosity, as he says, "was pretty, bright, and dense, and was 3" in diameter Surrounding this was a fainter glow, perhaps half a minute in diameter" If this observation can be verified, it will assuredly strengthen very considerably the hypothesis that the Nova was caused by collisions of meteorites, in the same way as the stars in the Pleiades nebula are the loci of intersecting streams, as clearly shown by Mr. Roberts' wonderful photographs

ABERRATION PROBLEMS<sup>1</sup>

EVERYBODY knows that to shoot a bird on the wing you must aim in front of it. Every one will readily admit that to hit a squatting rabbit from a moving train you must aim behind it.

These are examples of what may be called "aberration" from the sender's point of view, from the point of view of the source. And the aberration, or needful divergence between the point aimed at and the thing hit, has opposite sign in the two cases—the case when receiver is moving, and the case when source is moving. Hence, if both be moving, it is possible for the two aberrations to neutralize each other. So to hit a rabbit running alongside the train, you must aim straight at it.

If there were no air that is all simple enough. But every rifleman knows to his cost that though he fixes both himself and his target tightly to the ground, so as to destroy all aberration proper, yet a current of air is very competent to introduce a kind of spurious aberration of its own, which may be called windage, and that he must not aim at the target if he wants to hit it, but must aim a little in the eye of the wind.

So much from the shooter's point of view. Now attend to the point of view of the target.

Consider it made of soft enough material to be completely penetrated by the bullet, leaving a longish hole wherever struck. A person behind the target, whom we may call a marker, by applying his eye to the hole immediately after a hit, may be able to look through it at the shooter, and thereby to spot the successful man. I know that this is not precisely the function of an ordinary marker, but it is more complete than his ordinary function. All he does usually is to signal an impersonal hit, someone else has to record the identity of the shooter. I am rather assuming a volley of shots, and that the marker has to allocate the hits to their respective sources by means of the holes made in the target.

Well, will he do it correctly? assuming, of course, that he can do so if everything is stationary, and ignoring all curvature of path, whether vertical or horizontal curvature. If you think it over you will perceive that a wind will not prevent his doing it correctly, the line of hole will point to the shooter along the path of his bullet, though it will not point along his line of aim. Also, if the shots are fired from a moving ship, the line of hole in a stationary target will point to the position the gun occupied at the instant the shot was fired, though it may have moved since then. In neither of these cases (moving medium and moving source) will there be any aberration error.

But if the target is in motion, on an armoured train for instance, then the marker will be at fault. The hole will not point to the man who fired the shot, but to an individual ahead of him. The source will appear to be displaced in the direction of the observer's motion. This is common aberration. It is the simplest thing in the world. The easiest illustration of it is that when you run through a vertical shower, you tilt your umbrella forward, or, if you have not got one, the drops hit you in the face, more accurately, your face as you run forward hits the drops. So the shower appears to come from a cloud ahead of you, instead of from one overhead.

We have thus three motions to consider, that of the source, of the receiver, and of the medium, and of these only motion of receiver is able to cause an aberrational error in fixing the position of the source.

So far we have attended to the case of projectiles, with the object of leading up to light. But light does not consist of projectiles, it consists of waves, and with waves matters are a little different. Waves crawl through a medium at their own definite pace; they cannot be flung forwards or sideways by a moving source, they do not move by reason of an initial momentum which they are gradually expending, as shots do, their motion is more analogous to that of a bird or other self-propelling animal than it is to that of a shot. The motion of a wave in a moving medium may be likened to that of a rowing boat on a river. It crawls forward with the water, and it drifts with the water, its resultant motion is compounded of the two, but it has nothing to do with the motion of its source. A shot from a passing steamer retains the motion of the steamer as well as that given it by the powder. It is projected therefore in a slant direction. A boat lowered from the side of a passing steamer, and rowing off, retains none of the motion of its source, it is not projected, it is self-propelled. That is like the case of a wave.

<sup>1</sup> A lecture on "The Motion of the Ether near the Earth," by Dr. Oliver Lodge, at the Royal Institution, Friday evening, April 7, 1892.

The diagram illustrates the difference. Fig. 1 shows a moving cannon or machine gun, moving with the arrow, and firing a succession of shots which share the motion of the cannon as well as their own, and so travel slant. The shot fired from position 1 has reached A, that fired from the position 2 has reached B, and that fired from position 3 has reached C by the time the fourth shot is fired at D. The line ACD is a prolongation of the axis of the gun, it is the line of aim, but it is not the line of fire, all the shots are travelling slant this line, as shown by the arrows. There are thus two directions to be distinguished. There is the row of successive shots, and there is the path of any one shot. These two directions enclose an angle. It may be called an aberration angle, because it is due to the motion of the source, but it need not give rise to any aberration. True direction may still be perceived from the point of view of the receiver. Attend to the target. The first shot is supposed to be entering at A, and if the target is stationary will leave it at Y. A marker looking along YA will see the position whence the shot was fired. This may be likened to a stationary observer looking at a moving star. He sees it where and as it was when the light

FIG. 1

started on its long journey. He does not see its present position, but there is no reason why he should. He does not see its physical state or anything as it is now. There is no aberration caused by motion of source.

But now let the receiver be moving at same pace as the gun, as when two grappled ships are firing into each other. The motion of the target carries the point Y forward, and the shot A leaves it at Z, because Z is carried to where Y was. So in that case the marker looking along ZA will see the gun, not as it was when firing, but as it is at the present moment, and he will see likewise the row of shots making straight for him. This is like an observer looking at a terrestrial object. Motion of the earth does not disturb ordinary vision.

Fig. 2 shows as nearly the same sort of thing as possible for the case of emitted waves. The tube is a source emitting a succession of disturbances without momentum. ABCD may be thought of as horizontally flying birds, or as crests of waves, or

FIG. 2

they may even be thought of as bullets, if the gun stands still every time it fires, and only moves between whiles.

The line ABCD is now neither the line of fire nor the line of aim. It is simply the locus of disturbances emitted from the successive positions 1 2 3 4.

A stationary target will be penetrated in the direction AV, and this line will point out the correct position of the source when the received disturbance started. If the target moves, a disturbance entering at A may leave it at Z, or at any other point according to its rate of motion, the line ZA does not point to the source, and so there will be aberration when the target moves. Otherwise there would be none.

Now Fig. 2 also represents a parallel beam of light travelling from a moving source, and entering a telescope or the eye of an observer. The beam lies along ABCD, but this is not the direction of vision. The direction of vision to a stationary observer is determined not by the locus of successive waves, but by the path of each wave. A ray may be defined as the path of a labelled disturbance. The line of vision is YA, and coincides with the line of aim, which in the projectile case (Fig. 1) it did not.

The case of a revolving lighthouse, emitting long parallel beams of light and brandishing them rapidly round, is rather interesting. Fig. 3 may assist the thinking out of this case. Successive disturbances A, B, C, D, lie along a spiral curve, the spiral of Archimedes, and this is the shape of the beams as seen illuminating the dust particles, though the pitch of the spiral is too gigantic to be distinguished from a straight line. At first sight it might seem as if an eye looking along those curved beams would see the lighthouse slightly out of its true position, but it is not so. The true rays or actual paths of each disturbance are truly radial, they do not coincide with the apparent beam. An eye looking at the source will not look tangentially along the beam, but will look along AS, and will see the source in its true position. It would be otherwise for the case of projectiles from a revolving turret.

Thus, neither translation of star nor rotation of sun can affect direction. There is no aberration so long as the receiver is stationary.

FIG. 1

But what about a wind, or streaming of the medium past source and receiver, both stationary? Look at Fig. 1 again. Suppose a row of stationary cannon firing shots, which get blown by a cross wind along the slant *lay* (neglecting the curvature of path which would really exist). Still the hole in the target fixes the gun's true position, the marker looking along *ya* sees the gun which fired the shot. There is no true deviation from the point of view of the receiver, although the shots are blown aside and the target is not hit by the particular gun aimed at it. With a moving cannon, combined with an opposing wind, Fig. 1 would become very like Fig. 2.

(N.B.—The actual case, even without complication of spinning, &c., but merely with the curved path caused by steady wind-pressure, is not so simple, and there would really be an aberration or apparent displacement of the source towards the wind's eye—an apparent exaggeration of the effect of wind as shown in the diagram.)

In Fig. 2 the result of a wind is much the same, though the details are rather different. The medium is supposed to be drift-

FIG. 4

ing down across the field opposite to the arrows. The source is stationary at *s*. The arrows show the direction of waves in the medium, the dotted slant line shows their resultant direction. A wave centre drifts from *D* to *I* in the same time as the disturbance reaches *A*, travelling down the slant line *DA*. The angle between dotted and full lines is the angle between ray and wave movement. Now, if the motion of the medium inside the receiver is the same as it is outside, the wave will pass straight on along the slant to *Z*, and the true direction of the source is fixed. But if the medium inside the target or telescope is stationary, the wave will cease to drift as soon as it gets inside, under cover as it were; it will proceed along the path it has been really pursuing in the medium all the time, and make its exit at *Y*. In this latter case, of different motion of the medium inside and outside the telescope, the apparent direction, such as *YA*, is not the true direction of the source. The ray is in fact bent where it enters the differently-moving medium (as shown in Fig. 4).

NO. 1195, VOL. 46]

A slower moving stratum bends an oblique ray (slanting with the motion) in the same direction as a denser medium does. A quicker stratum bends it oppositely. If a medium is both denser and quicker moving, it is possible for the two bendings to be equal and opposite, and thus for a ray to go on straight. Parenthetically I may say that this is precisely what happens, on Fresnel's theory, down the axis of a water-filled telescope exposed to the general terrestrial ether drift.

In a moving medium waves do not advance in their normal direction, they advance slantways. The direction of their advance is properly called a ray. The ray does not coincide with the wave-normal in a moving medium.

All this is well shown in fig. 5.

FIG. 5

*S* is a stationary source emitting successive waves, which drift as spheres to the right. The wave which has reached *M* has its centre at *C*, and *CM* is its normal, but the disturbance, *M*, has really travelled along *SM*, which is therefore the ray. It has advanced as a wave from *S* to *r*, and has drifted from *P* to *M*. Disturbances subsequently emitted are found along the ray, precisely as in Fig. 2. A stationary telescope receiving the light will point straight at *s*. A mirror, *M*, intended to reflect the light straight back must be set normal to the ray, not tangential to the wave front.

The diagram also equally represents the case of a moving source in a stationary medium. The source, starting at *C*, has

FIG. 6

moved to *S*, emitting waves as it went, which waves as emitted spread out as simple spheres from the then position of source as centre. Wave-normal and ray now coincide. *SM* is not a ray, but only the locus of successive disturbances. A stationary telescope will look not at *s*, but along *MC* to the point where the source was when it emitted the wave *M*; a moving telescope, if moving at same rate as source, will look at *s*. Hence *SM* is sometimes called the apparent ray. The angle *SMC* is the aberration angle.

Fig. 6 shows normal reflection for the case of a moving source.

The mirror M reflects light received from  $S_1$  to a point  $S_2$ , just in time to catch the source there, as it travels steadily to the left.

Parenthetically I may say that the time taken on the double journey,  $S_1MS_2$ , is not quite the same as the double journey SMS when all is stationary, and that this is the principle of Michelson's great experiment referred to below.

For the rest of the lecture I am going to call the medium which conveys light, "ether" simply. Every one knows that ether is the light conveying medium, however little else they know about the properties of that tremendously important material.

We have arrived at this that a uniform ether stream all through space causes no aberration, no error in fixing direction. It blows the waves along, but it does not disturb the line of vision.

Stellar aberration exists, but it depends on motion of observer, and on motion of observer only. Etherial motion has no effect upon it, and when the observer is stationary with respect to object, as he is when using a terrestrial telescope, there is no aberration at all.

Surveying operations are not rendered the least inaccurate by the existence of a universal etherial drift, and they therefore afford no means of detecting it.

But observe that everything depends on the etherial motion being uniform everywhere, inside as well as outside the telescope, and along the whole path of the ray. If stationary anywhere it must be stationary altogether. There must be no boundary between stationary and moving ether, no plane of slip, no quicker motion even in some regions than in others. For (referring back to the remarks preceding Fig. 4) if the ether in receiver is stagnant while outside it is moving, a wave which has advanced and drifted as far as the telescope will cease to drift as soon as it gets inside, but will advance simply along the wave normal, and in general at the boundary of any such change of motion a ray will be bent, and an observer looking along the ray will see the source not in its true position, not even in the apparent position appropriate to his own motion, but lagging behind that position.

Such an aberration as this, a lag or negative aberration, has never yet been observed, but if there is any slip between layers of ether, if the earth carries any ether with it, or if the ether being in motion at all is not equally in motion everywhere throughout every transparent substance, then such a lag or negative aberration must occur in precise proportion to the amount of the carriage of ether by moving bodies.

On the other hand, if the ether behaves as a perfectly frictionless inviscid fluid, or if for any other reason there is no rub between it and moving matter, so that the earth carries no ether with it at all, then all rays will be straight, aberration will have its simple and well-known value, and we shall be living in a virtual ether stream of 19 miles a second, by reason of the orbital motion of the earth.

It may be difficult to imagine that a great mass like the earth can rush at this tremendous pace through a medium without disturbing it. It is not possible for an ordinary sphere in an ordinary fluid. At the surface of such a sphere there is a viscous drag, and a spinning motion diffuses out thence through the fluid so that the energy of the moving body is gradually dissipated. The persistence of terrestrial and planetary motions shows that etherial viscosity, if existent, is small, or at least that the amount of energy thus got rid of is a very small fraction of the whole. But there is nothing to show that an appreciable layer of ether may not adhere to the earth and travel with it, even though the force acting on it be but small.

This, then, is the question before us —

*Does the earth drag some ether with it? or does it slip through the ether with perfect freedom? (never mind the earth's atmosphere the part it plays is not important)*

In other words, is the ether wholly or partially stagnant near the earth, or is it streaming past us with the opposite of the full terrestrial velocity of nineteen miles a second? Surely if we are living in an ether stream of this rapidity we ought to be able to detect some evidence of its existence.

It is not so easy a thing to detect as you would imagine. We have seen that it produces no deviation or error in direction. Neither does it cause any change of colour or Doppler effect,

\* The word "stationary" is ambiguous. I propose to use "stagnant," as meaning stationary with respect to the earth, i.e. as opposed to stationary in space.

that is, no shift of lines in spectrum. No steady wind can affect pitch, simply because it cannot blow waves to your ear more quickly than they are emitted. It hurries them along, but it lengthens them in the same proportion, and the result is that they arrive at the proper frequency. The precise effects of motion on pitch are summarized in the following table —

#### *Changes of Frequency due to Motion*

Source approaching shortens waves

Receiver approaching alters relative velocity

Medium flowing alters both wave-length and velocity in exactly compensatory manner

What other phenomena may possibly result from motion? Here is a list —

#### *Phenomena resulting from Motion*

(1) Change or apparent change in direction, observed by telescope, and called aberration

(2) Change or apparent change in frequency, observed by spectroscope, and called Doppler effect

(3) Change or apparent change in time of journey, observed by lag of phase or shift of interference fringes

(4) Change or apparent change in intensity, observed by energy received by thermopile

Motion of either source or receiver can alter frequency, motion of receiver can alter apparent direction, motion of the medium can do neither, but surely it can hurry a wave so as to make it arrive out of phase with another wave arriving by a different path, and thus produce or modify interference effects.

Or again it may carry the waves down stream more plentifully than up stream, and thus act on a pair of thermopiles, arranged fore and aft at equal distances from a source, with unequal intensity.

And again, perhaps the laws of reflection and refraction in a moving medium are not the same as they are if it be at rest. Then, moreover, there is double refraction, colours of thin plates and thick plates, polarization angle, rotation of the plane of polarization, all sorts of optical phenomena.

It may be, perhaps, that in empty space the effect of an ether drift is difficult to detect, but will not the presence of dense matter make it easier? Consider No. 3 of the phenomena tabulated above.

I expect that everyone here understands interference, but I may just briefly say that two similar sets of waves "interfere" whenever and wherever the crests of one set coincide with and obliterate the troughs of the other set. Light advances in any given direction when crests in that direction are able to remain crests, and troughs to remain troughs. But if we contrive to split a beam of light into two halves, to send them round by different paths, and make them meet again, there is no guarantee that crest will meet crest and trough trough, it may be just the other way in some places, and wherever that opposition of phase occurs there there will be local obliteration or "interference." Two reunited half beams of light may thus produce local stripes of darkness, and these stripes are called interference bands.

If I can I will produce actual interference of light on the screen, but the experiment is a difficult one to make visible at a distance, partly because the stripes or bands of darkness are usually very narrow. I have not seen it attempted before. [Very visible bands were formed on screen by three mirrors, one of them semi-transparent, arranged as in Fig. 7.]

Now a most interesting and important, and I think now well-known, experiment of Fizeau proves quite simply and definitely that if light be sent along a stream of water, travelling inside the water as a transparent medium, it will go quicker with the current than against it. You may say that is only natural, a wind helps sound along one way and retards it the opposite way. Yes, but then sound travels in air, and wind is a bodily transfer of air; hence, of course, it gives the sound a ride, whereas light does not really travel in water, but always in ether. It is by no means obvious whether a stream of water can help or hinder it. Experiment decides, however, and answers in the affirmative. It helps it along with just about half the speed of the water, not with the whole speed, which is curious and important, and really means that the moving water has no effect whatever on the ether of space, though it would take too long to make clear how this comes about. Suffice for present purposes the fact that the velocity of light inside moving water, and therefore pre-

sumably inside all transparent matter, is altered by motion of that matter.

Does not this fact afford an easy way of detecting a motion of the earth through the ether? Here on the table is water travelling along 19 miles a second. Send a beam of light through it one way and it will be hurried, its velocity, instead

Fig. 7—Plan of interference kitescope

of being 140,000 miles a second, will be 140,009 miles. Send a beam of light the other way, and its velocity will be 139,991, just as much less. Bring these two beams together, surely some of their wave lengths will interfere. M. Hoek, Astronomer at Utrecht, tried the experiment in this very form, here is a diagram of his apparatus (Fig. 8). Babinet had tried another

Fig. 8

form of the experiment previously. Hoek expected to see interference bands, from the two half-beams which had traversed the water, one in the direction of the earth's motion and the other against it. But no interference bands were seen. The experiment gave a negative result.

An experiment, however, in which nothing is seen is never a

Fig. 9

very satisfactory form of a negative experiment, it is, as Mascart calls it, "doubly negative," and we require some guarantee that the condition was right for seeing what might really have been in some sort there. Hence Mascart and Yamin's modification of the experiment is preferable (Fig. 9). The thing now looked for is a shift of already existing interference bands, when the

above apparatus is turned so as to have different aspects with respect to the earth's motion, but no shift was seen.

Interference methods all fail to display any trace of relative motion between earth and ether.

Try other phenomena then. Try refraction. The index of refraction of glass is known to depend on the ratio of the speed of light outside, to the speed inside, the glass. If then the ether be streaming through glass, the velocity of light will be different inside it according as it travels with the stream or against it, and so the index of refraction will be different. Arago was the first to try this experiment, by placing an achromatic prism in front of a telescope on a mural circle, and observing the deviation it produced on stars.

Observe that it was an *achromatic* prism, treating all wave-lengths alike, he looked at the *deviated* image of a star, not at its *dispersed* image or spectrum, else he might have detected the change-of-frequency effect due to motion of source or receiver first actually seen by Dr. Huggins. I do not think he would have seen it, because I do not suppose his arrangements were delicate enough for that very small effect, but there is no error in the conception of his experiment, as Prof. Mascart has inadvertently suggested there was.

Then Maxwell repeated the attempt in a much more powerful manner, a method which could have detected a very minute effect indeed, and Mascart has also repeated it in a simple form. All are absolutely negative.

Well, what about aberration? If one looks through a moving stratum, say a spinning glass disk, there ought to be a shift caused by the motion (see Fig. 4). The experiment has not been tried, but I entertain no doubt about its result, though a high speed and considerable thickness of glass or other medium is necessary to produce even a microscopic apparent displacement of objects seen through it.

But the speed of the earth is available, and the whole length of a telescope tube may be filled with water, surely that is enough to displace rays of light appreciably.

Sir Geo. Airy tried it at Greenwich on a star, with an appropriate zenith sector full of water. Stars were seen through the water telescope precisely as through an air telescope. A negative result again.

Stellar observations, however, are unnecessarily difficult. Fresnel had said that a terrestrial source of light would do just as well. He had also (being a man of exceeding genius) predicted that nothing would happen. Hoek has now tried it in a perfect manner and nothing did happen.

Since then Prof. Mascart with great pert nacity has attacked the phenomena of thick plates, Newton's rings, double refraction, and the rotatory phenomenon of quartz, but he has found absolutely nothing attributable to a stream of ether past the earth.

The only positive result ever supposed to be attained was in a very difficult polarization observation by Fizeau in 1859. As this has not yet been repeated, it is safest at present to ignore it, though by no means to forget that it wants repeating.

Fizeau also suggested, but did not attempt, what seems an easier experiment, with fore and aft thermopiles and a source between them, to observe the drift of a medium by its convection of energy, but arguments based on the law of exchanges<sup>1</sup> tend to show, and do show as I think, that a probable alteration of radiating power due to motion through a medium would just compensate the effect otherwise to be expected.

We may summarize most of these statements as follows:—

#### Summary.

Source alone moving produces	A real and apparent change of wave length
	A real but not apparent error in direction.
	No lag of phase or change of intensity, except that appropriate to altered wave-length
Medium alone moving, or source and receiver moving together, produces	No change of frequency
	No error in direction
	A real lag of phase, but undetectable without control over the medium.
	A change of intensity corresponding to different distance, but compensated by change of radiating power.

<sup>1</sup> Lord Rayleigh (NATURE, March 25, 1892)

Receiver alone moving produces

An apparent change of wave-length  
An apparent error in direction  
No change of phase or of intensity,  
except that appropriate to different  
virtual velocity of light

I may say, then, that not a single optical phenomenon is able to show the existence of an ether stream near the earth. All optics goes on precisely as if the ether were stagnant with respect to the earth.

Well then perhaps it *is* stagnant. The experiments I have quoted do not prove that it is so. They are equally consistent with its perfect freedom and with its absolute stagnation, though they are not consistent with any intermediate position. Certainly, if the ether were stagnant, nothing could be simpler than their explanation.

The only phenomena then difficult to explain would be those depending on light coming from distant regions through all the layers of more or less dragged ether. The theory of astronomical aberration would be seriously complicated, in its present form it would be upset. But it is never wise to control facts by a theory: it is better to invent some experiment that will give a different result in stagnant and in free ether. None of those experiments so far described are really discriminative. They are, as I say, consistent with either hypothesis, though not very obviously so.

Mr. Michelson, however, of the United States, has invented a plan that will discriminate, and, what is much more remarkable, he has carried it out.

That it is an exceptionally difficult experiment you will realize when I say that the experiment will fail altogether unless one part in 400 millions can be clearly detected.

Mr. Michelson reckons that by his latest arrangement he could see 1 in 4000 millions if it existed (which is equivalent to detecting an error of  $\frac{1}{10^8}$  of an inch in a length of forty miles), but he saw nothing. Everything behaved precisely as if the ether was stagnant, as if the earth carried with it all the ether in its immediate neighbourhood. And that is his conclusion. If he can repeat it and get a different result on the top of a mountain, that conclusion may be considered established. At present it must be regarded as tentative.

I have not time to go into the details of his experiment (it is described in *Phil. Mag.* 1887), but I may say that it depends on no doubtful properties of transparent substances, but on the straightforward fundamental principle underlying all such simple facts as that—it takes longer to row a certain distance and back up and down stream than it does to row the same distance in still water, or that it takes longer to run up and down a hill than to run the same distance laid out flat, or that it costs more to buy a certain number of oranges at three a penny and an equal number at two a penny than it does to buy the whole lot at five for twopence.

Hence, although there may be some way of getting round Mr. Michelson's experiment, there is no obvious way, and I conjecture that if the true conclusion be not that the ether near the earth is stagnant, the experiment will lead to some other important and unknown fact.

The balance of evidence at this stage seems to incline in the sense that the earth carries the neighbouring ether with it.

But now put the question another way. Can matter carry neighbouring ether with it when it moves? Abandon the earth altogether; its motion is very quick, but too uncontrollable, and it always gives negative results. Take a lump of matter that you can deal with, and see if it pulls any ether along.

That is the experiment I set myself to perform, and which, in the course of the last year, I have performed.

I take a steel disk, or rather a couple of steel disks clamped together with a space between. I mount it on a vertical axis and spin it like a teetotum as fast as it will stand without flying to pieces. Then I take a parallel beam of light, split it into two by a semi-transparent mirror (Michelson's method), a piece of glass silvered so thinly that it lets half the light through and reflects the other half, and I send the two halves of this split beam round and round in opposite directions in the space between the disks. They may thus travel a distance of 20 or 30 or 40 feet. Ultimately they are allowed to meet and enter a telescope. If they have gone quite identical distances they need not interfere, but usually the distances will differ by a hundred thousandth of an inch or so, which is quite enough to bring about interference.

The mirrors which reflect the light round and round between the disks are shown in Fig. 10. If they form an accurate square the last two images will coincide, but if the mirrors are the least inclined to one another at any unaliquot part of  $360^\circ$  the last image splits into two, as in the kaleidoscope is well known, and the interference bands may be regarded as resulting from those two sources. The central white band bisects normally the distance between them, and their amount of separation determines the width of the bands. There are many interesting optical details here, but I shall not go into them.

The thing to observe is whether the motion of the disks is able to replace a bright band by a dark one, or *vice versa*. If it does, it means that one of the half beams, viz. that which is travelling in the same direction as the disks, is helped on a trifle, equivalent to a shortening of journey by some quarter millionth of an inch or so in the whole length of 30 feet, while the other half beam, viz. that travelling against the motion of the disks, is retarded, or its path virtually lengthened, by the same amount.

If this acceleration and retardation actually occurs, waves which did not interfere on meeting before the disks moved, will interfere now, for one will arrive at the common goal half a length behind the other.

Now a gradual change of bright space to dark, and *vice versa*, shows itself, to an observer looking at the bands, as a

FIG. 10.—Plan of steel disks one yard in diameter and optical frame, showing the light going round and round, three times each way, between the disks.

gradual change of position of the bright stripes, or a shift of the bands. A shift of the bands, and especially of the middle white band, which is much more stable than the others, is what we look for.

At first I saw plenty of shift. In the first experiment the bands sailed across the field as the disks got up speed until the crosswire had traversed a band and a half. The conditions were such that had the ether whirled at the full speed of the disks I should have seen a shift of three bands. It looked very much as if the light was helped along at half the speed of the moving matter, just as it is inside water.

On stopping the disks the bands returned to their old position. On starting them again in the opposite direction, the bands ought to have shifted the other way too; but they did not, they went the same way as before.

The shift was therefore wholly spurious; it was caused by the centrifugal force of the blast of air thrown off from the moving disks. The mirrors and frame had to be protected from this. Many other small changes had to be made, and gradually the spurious shifts have been reduced and reduced, largely by the skill and patience of my assistant, Mr. Davies, until now there is barely a trace of them.

But the experiment is not an easy one. Not only does the blast exert pressure, but at high speeds the churning of the air

makes it quite hot. Moreover, the tremor of the whirling machine, in which some four or five horse power is sometimes being expended, is but too liable to communicate itself to the optical part of the apparatus. Of course elaborate precautions are taken against this. Although the two parts, the mechanical and the optical, are so close together, their supports are entirely independent. But they have to rest on the same earth, and hence communicated tremors are not absent. They are the cause of all the slight residual trouble.

The method of observation now consists in setting a wire of the micrometer accurately in the centre of the middle band, while another wire is usually set on the first band to the left. Then the micrometer heads are read, and the setting repeated once or twice to see how closely and dependably they can be set in the same position. Then we begin to spin the disks, and when they are going at some high speed, measured by a siren note and in other ways, the micrometer wires are reset and read—reset several times and read each time. Then the disks are stopped and more readings are taken. Then their motion is reversed, the wires set and read again, and finally the motion is once more stopped and another set of readings taken. By this means the absolute shift of middle band and its relative interpretation in terms of wave-length are simultaneously obtained, for the distance from the one wire to the other, which is often two revolutions of a micrometer head, represents a whole wave-length shift.

In the best experiments I do still often see something like a fiftieth of a band shift, but it is caused by residual spurious causes, for it repeats itself with sufficient accuracy in the same direction when the disks are spun the other way round.

Of real reversible shift, due to motion of the ether, I see nothing. I do not believe the ether moves. It does not move at a five-hundredth part of the speed of the steel disks. I hope to go further, but my conclusion so far is that such things as circular saws, flywheels, railway trains, and all ordinary masses of matter do not appreciably carry the ether with them. Their motion does not seem to disturb it in the least.

The presumption is that the same is true for the ether, but the ether is a big body, it is conceivable that so great a mass may be able to act when a small mass would fail. I would not like to be too sure about the ether. What I do feel already pretty sure of is that if moving matter disturbs ether in its neighbourhood at all, it does so by some minute action, comparable in amount perhaps to gravitation, and possibly by means of the same property as that to which gravitation is due—not by anything that can fairly be likened to ethereal viscosity.

### NATIVE NEW ZEALAND BIRDS

FROM a scientific point of view it is of so much importance that native New Zealand birds should be protected that many naturalists will read with interest the following memorandum, which was drawn up by Lord Onslow, the late Governor of New Zealand, and presented to both Houses of the General Assembly by command of his Excellency—

It is admitted by naturalists that New Zealand possesses in some respects the most interesting avifauna in the world. It is a melancholy fact that, under the changed condition of existence this remarkable avifauna is passing away. Some of the species have already disappeared, whilst others are verging on extinction. Take, for example, the wingless birds of New Zealand. These diminutive representatives of the gigantic brevipennate birds which formerly inhabited New Zealand are objects of the highest interest to the natural historian. The kiwis, like their colossal prototypes the moas, once existed in very considerable numbers in almost every part of the country. At the time of the first colonization of New Zealand, fifty years ago, they were still abundant in all suitable localities. At the present day their last refuges may be indicated on the map without any difficulty. The North Island species (*Apteryx bulleri*) is still comparatively plentiful in the wooded heights of Pirongia and in the bosky groves of the Upper Wanganui. From all other localities where formerly numerous it has practically disappeared. The South Island kiwi (*Apteryx australis*) is now met with in only widely-scattered localities on the west coast. The small spotted or grey kiwi (*Apteryx owenii*), of which perhaps thousands could have been obtained a few years back, has succumbed to the ravages of the stoat and weasel, the persecution by wild dogs, and the necessities of roving

diggers, and it is only now to be found in any number along the lower wooded ranges of the Southern Alps. *Apteryx haasti* is one of our rarest species, and *Apteryx maxima* is strictly confined to the wooded parts of Stewart Island.

The kakapo, or ground parrot (*Strigops habroptilus*), which was formerly so abundant in the wooded country along the whole of the West Coast Sounds and on the western slope of the Southern Alps, is becoming a scarce bird. According to Mr Richardson, who recently read an exhaustive paper on the subject before the Otago Institute, both the kiwi and the kakapo are now confined to very restricted districts, within which, under the combined attacks of introduced wild dogs and cats, stoats, weasels, and ferrets, they are fast diminishing.

The blue-wattled crow and South Island thrush, which were every-day camp visitors when Sir James Hector explored the West Coast in 1863, are now very rarely seen, whilst in the North Island the native thrush and some of the smaller birds have disappeared altogether.

Prominent writers on zoological science, such as Prof Newton, of Cambridge, Prof Flower, at the head of the British Museum, and Dr Sclater, the accomplished secretary of the Zoological Society of London, have over and over again urged the importance of some steps being taken for the conservation of New Zealand birds, and they have pointed out that it will be a lasting reproach to the present generation of colonists if no attempt is made to save some—if only a remnant—of these expiring forms for the student of the future. Thus, Prof Newton, in his address to the Biological Section of the British Association, at Manchester, in 1887, said: "I would ask you to bear in mind that these indigenous species of New Zealand are, with scarcely an exception, peculiar to the country, and, from every scientific point of view, of the most instructive character. They supply a link with the past that, once lost, can never be recovered. It is therefore incumbent upon us to know all we can about them before they vanish. The forms we are allowing to be killed off, being almost without exception ancient forms, are just those that will teach us more of the way in which life has spread over the globe than any other recent forms, and for the sake of posterity, as well as to escape its reproach, we ought to learn all we can about them before they go hence and are no more seen."

The chief cause of the destruction of native birds is no doubt the introduction of foreign animals, against which the indigenous species are unable to contend successfully in the struggle for existence, especially under the changed conditions of life brought about by colonization. Probably the chief factor in this work of destruction is the Norway rat, whose introduction was of course unintentional, but an inevitable incident of settlement. The insectivorous and other birds introduced (whether wisely or not it is not necessary now to discuss) by our various acclimatization societies have, as it were, driven out and replaced many of the native species. These latter have succumbed to some general law of nature under which races of animals and plants yield to foreign invasion and rapidly disappear, the aboriginal races of man being no exception to this general rule. Where the causes themselves are recondite, it is, of course, difficult to find the means of counteracting them, but it is an observed law of nature that expiring races survive and linger longest in insular areas. That has been the experience of zoologists all over the world, the islands of Mauritius and Rodriguez presenting a striking instance in point. Here in New Zealand we have many similar evidences. The remarkable tuatara lizard (*Sphenodon punctatum*), supposed to be a survival from a very ancient fauna, and constituting, *per se*, a distinct order of reptilia, which years ago became extinct on the mainland (chiefly through the ravages of introduced wild pigs), still exists in very considerable numbers on the small islands lying off our coast. The makomako, or bell bird (*Anthornis melanura*), at one time the very commonest of our birds, although still plentiful in the South Island, has absolutely disappeared from every part of the North Island, but it still exists on the wooded islands of the Hauraki Gulf and Bay of Plenty, and on the island of Kapiti, in Cook Strait. The same remarks apply with almost equal force to the wood-robin (*Miro albifrons*) and the white head (*Chitonys albigapilla*), two species which have never inhabited the South Island at all. The stitch-bird (*Pogonornis cinerea*), which forms a sort of connecting link with the avifauna of Australia, was thirty years ago very plentiful in the woods surrounding Wellington, but it had long before disappeared from the northern parts of the island. It is now

extinct all over the mainland, but it exists in comparative plenty on the little Barrier Island—presumably the only locality in the world where this species is now to be found.

All these facts and considerations point to the conclusion that if an attempt is to be made to preserve these and other indigenous species, it must be by setting apart suitable islands for the purpose, and placing them under very strict protective regulations.

Assuming it to be granted that it is the duty of the Government to take the necessary measures, the next question is, what islands are the most suitable for the purpose?

After making careful inquiries on the subject, and reading much that has been written by the Chief Surveyor and other local authorities, I have come to the conclusion that the two best and most readily available islands are the Little Barrier at the north, and Resolution Island at the south.

1 *The Little Barrier*.—This island is still in the hands of the Maoris, but the Government is in negotiation for its purchase, and, as I understand there is only a small amount at issue between the parties, I would strongly urge its immediate acquisition for the purposes indicated. Not only is the Little Barrier known to be the habitat of the stitch bird, the white head, the bell-bird, and the native robin (all of which have practically disappeared from the mainland), but it has a wooded surface admirably adapted to the habits of such birds, it is easily accessible from Auckland, it would be difficult for any person to land and shoot birds there without at once attracting the attention of the many ships which are constantly passing in and out of the Hauraki Gulf.

2 *Resolution Island*.—This has now been proclaimed a reserve for native fauna and flora.

(1) Resolution Island is just at a convenient distance from the mainland. It is of considerable extent, with good harbours having deep water and safe anchorage.

(2) Several of the species that it is most desirable to preserve (such as kākapo and kiwi) are known to exist there already in considerable numbers.

(3) It is believed to be the final refuge of the great flightless rail (*Notornis mantelli*), only three specimens of which have ever been obtained in New Zealand, two of these being now in the National Museum, and the other in the Royal Museum at Dresden. One of those in the British Museum (obtained by Mr. Walter Mantell in 1849) was caught by a party of sealers at Duck Cove, on Resolution Island, and the other was captured by Maoris on Secretary Island, opposite to Dex's Cove, Thompson Sound. The third was taken as recently as 1881 by a party of rabbit hunters in the vicinity of Lake Te Anau. There is every reason to believe that this rare and interesting species still survives on the island which has now been set apart as a permanent Government reserve.

Looking to the interests involved—the great loss to the scientific world implied in the extermination of natural forms that do not exist elsewhere, and the importance, therefore, of saving them—it cannot be denied that a heavy responsibility rests on those who, while there is yet time and opportunity, may neglect to take the necessary steps for their preservation.

All that is wanted to rouse public interest in such a matter is actual knowledge of the facts. There is a strong sentiment always in the public mind against the final extirpation of any living species. As a proof of this one has only to read of the strong public feeling that exists in San Francisco in regard to the protection of the "sea lions" frequenting the famous Seal Rocks lying off the shore, and of the universal regret with which the Americans regard the almost complete extirpation of the herds of bison, of which at the present day only a small remnant survives under Government protection within certain "reservations." It finds further expression in the lament of all true sportsmen and naturalists on account of the disappearance, through wanton slaughter, of the large game of South Africa. Look, for example, at the quagga, which is now on the verge of extinction. Forty years ago this fine animal might be counted by thousands on every valley and plain of the Cape Colony. At the present day, besides three mounted specimens in European museums, there are two living examples in the Zoological Gardens. Take these away, and the species is blotted out completely.

In urging Ministers to take this subject under their serious consideration I may remind them that on December 16, 1886, the Secretary of the Auckland Institute wrote advising the purchase of the Little Barrier Island as a Government preserve,

and that the Premier, Sir Robert Stout, approved of this being done. The purchase was, I believe, strongly advocated by Prof. Thomas and by Mr. A. Reischek, the Austrian collector, both of whom had visited the island and inspected every part of it. At a recent meeting of the Otago Institute a resolution was passed authorizing the Council of that body to move the Government to proclaim Resolution Island for this purpose.

Resolution Island having now been so proclaimed, I would suggest that steps should be immediately taken for ascertaining to what extent Resolution Island is already stocked with kiwi and kākapo, that a sufficient supply of these and other birds be at once obtained by purchase or otherwise from the mainland before it is too late, and turned loose both on this island and on the Little Barrier, and that Captain Fairchild (who takes a keen interest in this project) should be instructed to call at these islands from time to time during the periodical cruises of the *Hinemoa*, to ascertain if the birds are thriving, and to report results, with such practical suggestions and recommendations as he may be able to make for the furtherance of this plan of conservation.

I would also, at the same time, suggest that Ministers should take into consideration the propriety of including some other native birds on the list of protected species. As I have already mentioned, the bell-bird, formerly so plentiful, has entirely disappeared from the North Island. But it is still very plentiful all over the South Island, and is a common denizen of the gardens and shrubberies in all the principal towns. This is the bird that so enchanted Captain Cook by its song when his ship lay at anchor in Queen Charlotte Sound more than a hundred years ago, and, having become historical, it would be a grievous pity for the bird to die out altogether. The general testimony goes to show that the protection extended to the tus had the desired effect, this species being now more numerous everywhere than it was fifteen years ago. Would it not be well to extend the same protection to its small congener the makomako, whose haunts and habits are almost precisely similar?

Then, again, there is a bird famous in Maori history and poetry—remarkable for its singular beauty, and interesting to naturalists on account of its aberrant generic characters—a species confined to a very limited portion of the North Island, from which, owing to the eagerness of natural history collectors and the inevitable progress of settlement in its native woods, it is fast disappearing.

I refer, of course, to the huiā (*Helaloe ha acutirostris*), a bird which is naturally confined within such narrow geographical boundaries that I may describe its range as being limited to the Ruahine, Tararua, and Kimutaka Mountain ranges, with their divergent spurs and the intervening wooded valleys. The white-tipped tail-feathers of this beautiful bird have been from time immemorial the chief adornment of Maori chiefs as head-plumes, and an incident connected therewith, in ancient times, led to the adoption of the name by the great ancestors of the Ngāthiua Tribe.

As Ministers are aware, when selecting a Maori name for my infant son, to commemorate his New Zealand birth, I was induced, for several considerations, to give this name the preference over all others submitted to me, and I should therefore accept it as a compliment to my family if Ministers would exercise the power they possess and throw over this bird the shield of Government protection.

I ask this the more readily on the ground that I have been moved to do so by the chiefs of the Ngāthiua Tribe. At the public function at Otaki, on the 12th September last, when I had the pleasure of presenting my son to the assembled tribes, a number of very complimentary speeches were made by the leading chiefs, and one of them, in referring to the name, said, "There, yonder, is the snow-clad Ruahine range, the home of our favourite bird. We ask you, O Governor, to restrain the pakehas from shooting it, that when your boy grows up he may see the beautiful bird which bears his name."

The huiā loves the deep shade of the forest, and as its home is invaded by the settler's axe it would, if protected from reckless destruction, simply retire higher up the wooded ranges, till it finally took refuge in the permanent forest reserve, which embraces all the wooded mountain-tops within its natural domain. Under vigilant protection, therefore, the huiā would have every chance of being preserved and perpetuated.

Christchurch, Christmas Day, 1891.

ONSLOW

## A CENTURY OF SCIENTIFIC WORK

EVERYONE interested in science is aware that the "Société de Physique et d'Histoire Naturelle de Genève" has won for itself an honoured place among the learned Societies of the Continent. Work of the highest interest and importance has been done by many of its ordinary members, and the list of its honorary members includes a very large number of the investigators who, in different parts of Europe, have contributed most effectually to scientific progress. Some time ago this excellent Society celebrated the hundredth anniversary of its foundation, and an interesting supplementary volume has now been issued in memory of the occasion. To this volume Dr A. H. Wartmann contributes a sketch of the Society's history, and it may be worth while to note some of the facts he has recorded.

Nominally, the Society was founded in 1790. That is, several men of science in Geneva agreed in that year to unite in forming it. As a matter of fact, however, the first official meeting was not held until 1791. The Society was called at first the "Société des Naturalistes Genevois," and there were eight members, who met in each other's houses on the second and fourth Thursday of every month. The President was M. Gosse. A secretary and a treasurer were appointed, the annual subscription was fixed at two crowns, and an effort was made to obtain copies of the scientific journals of the time. It was felt that there ought to be more than eight members, so the honour of membership was offered to several men of science, by the majority of whom it was accepted. Foreign men of science who happened to be passing through Geneva were invited by the President to attend the meetings, and some of them were made honorary members. In the course of the first year M. Jurine made a present of his herbarium to the Society, this was the origin of its collections. One of the first objects of the Society was the creation of a botanic garden, and a site was chosen which has ever since been retained. M. Micheli presented a hot-house, exotic plants and seeds were obtained, and courses of instruction in botany were given under the Society's auspices by MM. Micheli and de Saussure.

The most eminent representative of science in Geneva at this time was Charles Bonnet. He was asked to become the patron or Honorary President of the new Society. He would have preferred the position of *confrère*, but ended by complying with the request. He died in 1793, bequeathing to the Society 300 crowns, which provided for the maintenance of a gardener and other necessary expenses in the botanic garden.

The activity of the young Society was shown in a series of labours in the physical and natural sciences—labours of which an account has been given by Vaucher, one of the founders. The question of a diploma of reception was raised, and, after much consideration, a seal was prepared. This was abandoned in 1819 in favour of a seal engraved by Bovy.

In 1792 the Society changed its name to "Société Genevoise d'Histoire Naturelle." Shortly afterwards the name by which the Society is still known was adopted.

Under an impulse due to M. d'Albert Henri Gosse, two other scientific Societies were founded in Geneva. One, created in 1803, went back to the name of "Société des Naturalistes." In 1829 it was merged in the "Société de Physique et d'Histoire Naturelle," in whose archives its papers are preserved. Many of these, according to M. Wartmann, are of some importance. The other Society was the "Société Helvétique des Sciences Naturelles," founded in 1815. Of this Society, which has continued to flourish, the "Société de Physique" may be regarded as the Genevese section. When it met at Geneva, in 1866, the two Societies united in the ceremony at the unveiling of a monument to M. Gosse.

When the number of members increased, a fixed place of meeting became necessary. They met for some years at the Société des Arts, then (from 1826) at the Académie Museum, and afterwards (from 1872) in the hall of the Société des Arts. The times of meeting were changed from the second and fourth to the first and third Thursday of every month, and in 1834 it was decided that a meeting should be held only on the first Thursday of the month.

The President holds office for a year. A Vice-President is also appointed. From 1858 to 1879 the President entered upon his duties in July, and in the following June he was succeeded by the Vice-President. Now the President and Vice-President assume office at the beginning of the year.

The Society consists of active members, emeritus members,

and honorary members. The former—limited in 1822 to forty, in 1863 to fifty, in 1878 to sixty—reside in the canton. The emeritus members are members who have ceased to take an active part in the Society's work. The honorary members—limited in 1859 to seventy, in 1878 to sixty—are chosen from among men of science in Switzerland or any other part of the world. There are also "associés libres," who cannot be appointed before the age of twenty-five.

Although women do not habitually attend the meetings, there is nothing to prevent them from being connected with the Society. Mrs. Somerville was an honorary member from 1834 to 1873.

Very many communications submitted to the Society have marked important stages in the development of science. At first some of the communications used to appear in foreign periodicals or in the *Bibliothèque Britannique*, which afterwards became the *Bibliothèque Universelle*. In 1820 it was decided that a collection of Memoirs should be issued, and that the task of selecting the papers should be intrusted to a Committee of Publication. This Committee still exists, its secretary being known as the corresponding secretary. The first volume, consisting of two numbers, appeared in 1821 and 1822, and in 1890 appeared the second part of the thirtieth volume. The publication of the Memoirs, many of which are accompanied with plates, is very costly, but sometimes the writers bear the whole or a part of the expense. A *Bulletin*, presenting a *résumé* of the proceedings, has been issued regularly since 1884, and an account has also been given since 1883 in the *Archives des Sciences Physiques et Naturelles*.

The funds of the Society are derived from subscriptions, gifts, and bequests. At first the amount of the annual subscription varied in accordance with the Society's needs, but in 1860 it was fixed at twenty francs. From 1829 to 1854 the Society was officially recognized by the State as the "Société Cantonale de Physique et d'Histoire Naturelle," and received an annual subsidy, but during the last thirty-eight years there has been no relation of this kind between the Society and the Government. A sum of 1200 francs is paid annually by the Administrative Council for the books and memoirs with which the Society enriches the public library of Geneva.

The various collections possessed by the Society have been given partly to the Museum of Natural History, partly to the Botanic "Conservatoire." A prize of 500 francs is offered every five years for the best essay on a genus or family of plants. The sum of 2400 francs which enables this prize to be offered was left to the Society for the purpose in 1841 by A. P. de Candolle. Since 1886 the Society has reserved for itself, at a cost of 600 francs per annum, a place at the Zoological Laboratory of Villefranche, and the person who is to be allowed to take advantage of it is chosen in accordance with a fixed set of rules.

The Society now includes fifty-four ordinary members, four emeritus members, fifty honorary members, and thirty-one *associés libres*. Among the honorary members are many of the most eminent men of science in Europe and America.

## THE TRANSMISSION OF ACQUIRED CHARACTERS THROUGH HEREDITY

THE bearing of insects upon this subject is very clearly brought out by Prof. C. V. Riley in a recently published paper on "Some Interrelations of Plants and Insects" read before the Biological Society of Washington. After dealing with the facts connected with the insects associated with the interesting plants of the genus *Yucca* and the pollination of their flowers by the *Yucca* Moth, and touching briefly upon certain aspects of fig-caprification, he makes the following remarks—

"Now, when it comes to the bearing which the history of these little moths has upon some of the larger questions that are now concerning naturalists (for instance, the transmission of acquired characters, or the origin, development, and nature of the intelligence displayed by the lower animals), broad fields of interesting opinion and conclusion open up before us—fields that cannot possibly be explored without trenching too much upon your time. I will close, therefore, with a few summary expressions of individual opinion, without attempting to elaborate the reasons in detail, and with the object of eliciting further discussion, which is one of the objects of the paper. My first conviction is that insect life and development give no

countenance to the Weissman school, which denies the transmission of functionally acquired characters, but that, on the contrary, they furnish the strongest refutation of the views urged by Weissman and his followers. The little moths of which I have been speaking, and indeed the great majority of insects—all, in fact, except the truly social species—perform their humble parts in the economy of nature without teaching or example, for they are, for the most part, born orphans, and without relatives having experience to communicate. The progeny of each year begins its independent cycle anew. Yet every individual performs more or less perfectly its allotted part, as did its ancestors for generation after generation. The correct view of the matter, and one which completely refutes the more common idea of the fixity of instinct, is that a certain number of individuals are, in point of fact, constantly departing from the lines of action and variation most useful to the species, and that these are the individuals which fail to perpetuate their kind and become eliminated through the general law of natural selection.

"Whether these actions be purely unconscious and automatic or more or less intelligent and conscious, does not alter the fact that they are necessarily inherited. The habits and qualities that have been acquired by the individuals of each generation could have become fixed in no other way than through heredity. Many of these acts, which older naturalists explained by that evasive word "instinctive," may be the mere unconscious outcome of organization, comparable to vegetative growth, but insects exhibit all degrees of intelligence in their habits and actions, and they perform acts which, however voluntary and, as I believe, conscious in many cases, as in that of our Yucca Moth, could not be performed were the tendency not inherited. Every larvæ which spins or constructs a hibernaculum, or a cocoon in which to undergo its transformations, exemplifies the potent power of heredity in transmitting acquired peculiarities. A hundred species of parasitic larvæ, e.g., of the family Braconidæ, which in themselves are almost or quite indistinguishable from one another structurally, will nevertheless construct a hundred distinctive cocoons—differing in form, in texture, in colour and in marking—each characteristic of its own species, and in many instances showing remarkable architectural peculiarities. These are purely mechanical structures, and can have little or nothing to do with the mere organization or form or structure of the larva, but they illustrate in the most convincing manner the fact that the tendency to construct, and the power to construct, the cocoon after some definite plan, must be fixed by heredity, since there is no other way of accounting for it. This fact alone, which no one seems to have thought of in the discussion, should be sufficient to confound the advocates of the non-transmissibility of acquired characteristics.

"Thus, to my view, modification has gone on in the past, as it is going on at the present time, primarily through heredity in the insect world. I recognize the physical influence of environment, I recognize the effect of the interrelation of organisms, I recognize, even to a degree that few others do, the psychic influence, especially in higher organisms—the power of mind, will, effort, or the action of the individual as contradistinguished from the action of the environment. I recognize the influence of natural selection, properly limited, but above all as making effective and as fixing and accumulating the various modifications due to these or whatever other influences, I recognize the power of heredity, without which only the first of the influences mentioned can be permanently operative."

#### FORTHCOMING SCIENTIFIC BOOKS.

AMONG Messrs. MACMILLAN AND Co.'s announcements are the following books—"Evolution and Man's Place in Nature," by Prof. H. Calderwood, "A Primer of Practical Horticulture," by J. Wright; "A Text-book of Tropical Agriculture," by H. A. Nicholls, M.D., F.L.S., C.M.Z.S., with illustrations, "The Food of Plants," by A. P. Laurie, "Metal Colouring and Bronzing," by Arthur H. Horns, "Differential Calculus for Schools," by Joseph Edwards, "The Beauties of Nature and the Wonders of the World we live in," by the Right Hon. Sir John Lubbock, Bart., M.P., F.R.S., with illustrations, "Finger Prints," by Francis Galton, F.R.S., with numerous illustrations, "Hereditary Genius: an Inquiry into its Laws and Consequences," by Francis Galton, F.R.S., new edition, "Materials for the Study of Variation in Animals," Part I, discontinuous variation, by William Bateson, illustrated; "On

Colour Blindness," by Thomas H. Bickerton, illustrated (NATURE series), Hygiene its Principles as applied to Public Health, adapted to the requirements of the Elementary and Advanced Stages of the Science and Art Department, &c., by Edward F. Willoughby, M.B., new and enlarged edition, "A Uniform Edition of Prof. Huxley's Essays, Uniform with the works of Emerson, John Morley, &c., in 6 vols., comprising Lay Sermons, Addresses and Reviews, Critiques and Addresses, Science and Culture, American Addresses, Man's Place in Nature," &c., "Atlas of Classical Antiquities," by Th. Schreiber, edited for English use by Prof. W. C. F. Anderson, "Researches on the Propagation of Electrical Force," by Prof. Heinrich Hertz, authorized translation by Prof. D. E. Jones, B.Sc., illustrated, "A Text-book of Pathology Systematic and Practical," by Prof. D. J. Hamilton, "Electrical Papers," by Oliver Heaviside, "Pioneers of Science," by Prof. Oliver Lodge, with portraits and other illustrations, "The Diseases of Modern Life," by B. W. Richardson, M.D., new and cheaper edition, "The Theory and Practice of Absolute Measurements in Electricity and Magnetism," by Prof. A. Gray, Vol. II, and "A Theory of Wages and its Application to the Eight Hours Question and the Labour Problems," by Herbert M. Thompson.

Mr. MURRAY announces—"Explosives and Their Powers," translated and condensed from the French of M. Berthelot, by C. Napier Blake and William MacNab, with an introduction by Lt. Colonel J. P. Cundill, R.A., H.M. Inspector of Explosives, with illustrations, "Charles Darwin," a Biography, founded on the "Life and Letters of Charles Darwin," by his son, Francis Darwin, F.R.S., with portrait and illustrations, "The Collected Works of Werner Von Siemens," translated by E. F. Bamber, vol. ii "Applied Science," with illustrations, "Notes by a Naturalist on H.M.S. Challenger," a record of observations made during the voyage of H.M.S. Challenger round the world in the years 1872-76, under the command of Captain Sir G. S. Nares, R.N., K.C.B., F.R.S., and Captain F. T. Thomson, R.N., by H. N. Moseley, F.R.S., a new and cheaper edition, with portrait and numerous woodcuts, "Records of a Naturalist on the Amazons during Eleven Years' Adventure and Travel," by Henry Walter Bates, a new edition of the unabridged work, with a memoir of the author by Edward Clodd, with portrait, illustrations, and map, "The English Flower Garden Design, Views, and Plants," by W. Robinson, third edition, entirely revised, with many fine additional engravings, "A Manual of Naval Architecture," for the use of officers of the Navy, the Mercantile Marine, ship-owners, ship builders, and yachtsmen, by W. H. White, C.B., F.R.S., third edition, thoroughly revised and in great part rewritten, with 150 illustrations, "Outlines of Ancient Egyptian History," based on the work of Auguste Mariette, translated and edited, with notes, by Mary Brodrick, a new and revised edition, "The Metallurgy of Iron and Steel," by the late John Percy, M.D., F.R.S., a new and revised edition, with the author's latest corrections, and brought down to the present time, by H. Bauerman, F.G.S., with illustrations, "Studies in Modern Geology," by Dr. R. D. Roberts, "The Physiology of the Senses," by Professor McKendrick and Dr. Snodgrass, with illustrations, "Outlines of Modern Botany," by Prof. Patrick Geddes, "Logic, Inductive and Deductive," by Prof. Minto, "Psychology: A Historical Sketch," by Prof. Seth, "An Introduction to Physical Science," by John Cox, and "The History of Astronomy," by Arthur Berry.

Among the books in active preparation at the CLARENDON PRESS may be mentioned—"The Logic of Hegel," translated by W. Wallace, new edition, "Mathematical Papers of the late Henry J. S. Smith, Savilian Professor of Geometry in the University of Oxford," with portrait and memoir, 2 vols. quarto, "Researches in Stellar Parallax by the Aid of Photography" (Astronomical Observations made at the University Observatory, Oxford, fasc. iv), by C. Pritchard, D.D., F.R.S., a supplementary volume to Prof. Clerk Maxwell's "Treatise on Electricity and Magnetism," by J. J. Thomson, "A Manual of Crystallography," by M. H. N. Story-Maskelyne, "Elementary Mechanics," by A. L. Selby, "Analytical Geometry," by W. J. Johnston, "A Treatise on the Kinetic Theory of Gases," by H. W. Watson, D.Sc., new edition, "Hydrostatics and Elementary Hydrokinetics," by G. M. Minchin, "A Text-book of Pure Geometry," by J. W. Russell, "Catalogue of Eastern and Australian *Lepidoptera Heterocera* in the Collection of the Oxford University Museum," by Colonel C. Swinhoe.

and "Epidemic Influenza a Study in Comparative Statistics," by F A Dixey, D M

THE CAMBRIDGE UNIVERSITY PRESS promises — "The Collected Mathematical Papers of Prof Arthur Cayley, Sc D, F R S," vol v, "A History of the Theory of Elasticity and of the Strength of Materials," by the late I Todhunter, Sc D, F R S, edited and completed by Prof Karl Pearson, vol ii, Saint Venant to Lord Kelvin (Sir William Thomson), "A Treatise on Analytical Statics," by E J Routh, Sc D, F R S, vol ii, "A Treatise on the Theory of Functions of a Complex Variable," by A R Forsyth, Sc D, F R S, "The Jurassic Rocks of Cambridge," being the Sedgwick prize essay for the year 1886, by the late T Roberts, M A, "Fossil Plants as Tests of Climate," being the Sedgwick prize essay for 1892, by A C Seward, M A, "An Elementary Treatise on Plane Trigonometry," by E W Hobson, Sc D, and C M Jesop, "Euclid's Elements of Geometry, Books v and vi," by H M Taylor, "Mechanics and Hydrostatics for Beginners" (this book will include those portions of these subjects which are required for the Matriculation Examination of the University of London, by S L Loney), and "Solutions to the Exercises in Euclid, Books i-iv," by W W Taylor

Messrs WHITTAKER AND CO announce — Prof Oliver Lodge's "Treatise on Lightning Conductors and Lightning Guards," "A Comprehensive Work on the Dynamo," by C C Hawkins and F Wallis, "Coal Pits and Pitmen," by R Nelson Boyd, M Inst C E, "Pattern-Making for Students in Technical Schools and Apprentices," by a Foreman Pattern Maker, "Fitting for Engineer Students and others," by the same author, "Electrical Experiments," by G P Bonney, "Practical Electric Light Fitting," by F C Allsop, "Electric-Lighting and Power-Distribution," by W Perren Maycock, M I E E, "How to Manage a Dynamo," by S R Bottone, "The Manufacture of Soap," by W Lawrence Gadd, F I C, F C S, "Ship's Carpentry," by M and A Mowat, "Hammered Metal Work," by C G Leland, author of "Wood-Carving" and "Leather Work" In the Library of Popular Science — "Electricity and Magnetism," by S R Bottone, "Chemistry," by T Bolas, F I C, F C S, "Geology," by A J Jukes Browne, F G S, and other Volumes An Important Work for Medical Students — "Dissections Illustrated," a Graphic Handbook for Students of Human Anatomy, by C Gordon Brodie, F R C S, with Plates, carefully drawn and put on the stone by Percy Highley, from dissections of the human body made by the Senior Demonstrator of Anatomy at the Middlesex Hospital Medical School, the first part of which, with 17 coloured plates of the upper limb, two thirds natural size, will be issued immediately

In Mr STANFORD'S list attention is drawn to — A translation into English by Dr Hatch of Dr Theodor Posewitz's work on "Borneo its Geology and Mineral Resources" (the translator has added a number of references and notes, and four new maps accompany the translation), a new book by Mr Edward North Buxton, being an account of his adventures in pursuit of large game in various parts of the world (it will be entitled "Short Stalks or Hunting Camps, North, East, South, and West," and will be accompanied by a number of original illustrations), the paper on "The Fayûm and Lake Moeris," which Major R Hanbury Brown communicated to the recent Oriental Congress, with photographs by the author, diagrams, and a new map, "Castorologia or the Traditions of a Canadian Beaver," by Mr Horace T Martin, of Montreal (the work will be a handsome octavo, with a number of maps and illustrations), "The Partition of Africa," by Mr J Scott Keltie, Secretary to the Royal Geographical Society (it will be brought well up to date, and supplied with an excellent apparatus of maps), and new Editions of the following "Tanganyika Eleven Years in Central Africa," by Captain Hore; the late Sir Andrew Ramsay's "Physical Geology and Geography of Great Britain," revised by Mr W Topley, F G S.; Prof James Geikie's "Great Ice Age," thoroughly revised; and the late Sir Charles Anderson's "Lincoln Guide," revised by the Rev A R Maddison, Librarian and Succesor of Lincoln Cathedral

Messrs. BAILLIÈRE, TINDALL AND COX have in the press — "A Manual of Practical Medical Electricity," by Dawson Turner, M D, F R C P Ed, M R C P Lond; "The Practical Guide to the Public Health Acts and Correlated Acts for Officers of Health and Inspectors of Nuisances," by Thos Whiteside Hime, M D, second edition, enlarged; "Modern Ther-

apeutics, Medical and Surgical, including the Diseases of Women and Children," by Geo H Napheys, M D, ninth edition, revised and enlarged by Drs Allen Smith and Aubrey Davis, vol i, Medical, "Diseases of the Throat and Nose," a Practical Guide to Diagnosis and Treatment, with 220 typical illustrations in chromo lithography and numerous wood engravings, by Lennox Browne, F R C S Edin, fourth edition

Messrs WILLIAMS AND NORCOTE will publish — "Against Dogma and Free Will," by H Croft Hillier, in which the author wishes to prove from the discoveries of Weismann the impossibility of Free Will, the certainty of Science, and the uselessness of Metaphysics, and in two volumes "The Supernatural its Origin, Nature, and Evolution," by John H King, in which the author treats first of the origin and nature of Supernatural Concepts, and then of the evolution of the Supernatural in various nations and its modern presentations

Messrs GURNEY AND JACKSON have ready for immediate publication — "Odorographia," a Natural History of Raw Materials and Drugs used in the Perfume Industry, by I Ch Sawyer, F L S, "The Birds of Lancashire," by F S Mitchell, second edition, revised and annotated by Howard Saunders, F L S, etc, with additions by R J Howard, and other local authorities, a fourth edition of "Destructive Distillation," by Dr Mills, F R S, and a book on "Wild Spain," by Abel Chapman and Walter J Buck, treating of the beasts and birds of the Peninsula, deer, ibex, chamois, wild boar, and lynx, and bustards, flamingoes, eagles, vultures, game, and wild fowl, with more than 150 illustrations

Messrs SAMPHON LOW AND CO, LIMITED, have in hand — "The Student's Chemistry," by R L Taylor, F I C, F C S, fully illustrated, and "The Glacial Nightmare," by Sir Henry H Howorth, M P, 2 vols

Messrs CASSILL AND CO, LIMITED, announce "The Dawn of Astronomy, by J Norman Lockyer, F R S, "Beetles, Butterflies, Moths, and other Insects," a brief introduction to their collection and preservation, by A W Kappel, F L S, F E S, and W Fgmont Kirby, with 12 coloured plates, "Cassell's Storehouse of General Information," Vol III, fully illustrated with high class wood engravings, and with maps and coloured plates, "The Year-Book of Science" (second year of issue), edited by Prof Bonney, F R S, and containing contributions by leading scientific writers, Popular editions of Figuier's works revised by eminent British authorities, "The Insect World," "Reptiles and Birds" (new volumes), and "The Year-Book of Treatment for 1893," a critical review for practitioners of medicine and surgery

Messrs CHAS GRIFFIN AND CO, LIMITED, will issue "Diseases of the Heart (Diagnosis of)," by A Ernest Sansom, M D, F R C P, with 13 plates and illustrations in the text, "Ruptures, a Treatise on," by J F C Macready, F R C S, with numerous plates engraved on the stone after photographs, "Clinical Diagnosis the Chemical, Microscopical, and Bacteriological Evidence of Disease," by Prof von Jaksch, of Prague, translated from the third German edition by Jas Cagney, M D, with additional illustrations, many in colours, second edition, "The Diseases of Children Medical and Surgical," by H Bryan Donkin, M B, F R C P, and Bilton Pollard, M D, F R C S, "Gynecology," a practical treatise on, by J Halliday Croom, M D, with the collaboration of MM. Milne Murray, M B, and Johnson Symington, M D, "Midwifery," a practical treatise on, by John Phillips, M D, "A Manual of Obstetrics," for the use of students, nurses, and midwives, by Arch. Donald, M D, "Forensic Medicine and Toxicology" (a text book of), by J Dixon Mann, M D, F R C P, "A Medical Handbook for the Use of Students," by R S Aitchison, M B, F R C P, Edin, "Inorganic Chemistry" (a Text-Book of), by Dr Dupré, F R S, and Dr Wilson Hake, second edition, revised, "Mind in Matter," by the Rev James Tall, third edition, revised and enlarged, with special reference to later Darwinism, "Biology" (a Text-Book of), by Prof J R Ainsworth Davis, new edition, revised and enlarged, in two parts (1) Vegetable Morphology and Physiology, (2) Animal Morphology and Physiology, with additional illustrations, "Coal Mining" (a Text-Book of), by H W Hughes, F G S, with frontispiece and 490 illustrations, reduced from working drawings; "Ore and Stone Mining," by Prof. C Le Neve Foster, D Sc, with numerous illustrations; "Dyeing" (a manual of), for the use of practical dyers, manufacturers, and students, by Dr Knecht, Chr Rawson, and Dr. R Loewenthal, with numerous illustrations and specimens of dyed fabrics,

"Oils, Fats, Waxes, and Allied Materials, and the Manufacture therefrom of Candles, Soaps, and other Products," by C R Alder Wright, D Sc, F R S, with numerous illustrations, "Painters' Colours, Oils, and Varnishes" (a practical Manual), by Geo H Hurst, with illustrations, "Applied Mechanics (an Elementary Manual of), for first year students, by Prof A Jamieson, F R S E, with very numerous illustrations, and "Griffin's Electrical Price Book," for the use of electrical, civil, marine, and borough engineers, local authorities, architects, railway contractors, &c, edited by H J Dowsing

MESSRS SWAN SONNENSCHNEIN AND Co's list contains — "Text Book of Embryology Man and Mammals," by Dr Oscar Hertwig, translated and edited from the third German edition by Dr E L Mark, fully illustrated, "Text-Book of Embryology Invertebrates," by Drs Korschelt and Heider, translated and edited by Dr F L Mark and Dr W M Woodworth, fully illustrated, "Text Book of Comparative Geology," adapted from the work of Dr Kayser, by Philip Lake, fully illustrated, "Text Book of Palaeontology for Zoological Students," by Theodore F Groom, fully illustrated, "Text Book of Petrology," by F H Hatch, D Sc, a revised and enlarged edition of "An Introduction to the Study of Petrology," with 86 illustrations, "Handbook of Systematic Botany," by Dr F Warming, translated and edited by M C Potter, fully illustrated "Practical Bacteriology," by Dr Migula, translated and edited by H J Campbell, M D, "The Geographical Distribution of Disease in England and Wales," by Alfred Haviland, M D, with several coloured maps, "A Treatise on Public Hygiene and its applications in different European Countries," by Dr Albert Palmberg, translated, and the English portion edited and revised, by Arthur Newsholme, M D, fully illustrated, "The Photographer's Pocket Book," by Dr E Vogel, translated by F C Conrid, illustrated, "The Recrudescence of Leprosy and the Report of the Leprosy Commission," by William Lebb, "Roaring in Horses: its Pathology and Treatment," by P J Cadot, translated by Thomas J Watt Dollar, M R C V S "Introductory Science Text-Books," additions—Introductions to the Study of "Zoology," by B Lindsay, illustrated, "The Amphioxus," by Dr B Hatschek and James Luckey, illustrated, "Geology," by Edward B Aveling, D Sc (Lond), illustrated, "Physiological Psychology," by Dr Th Ziehen, adapted by Dr Otto Beyer and C C Vanlieu, with 21 illustrations, "Biology," by H J Campbell, M D "Young Collector Series" additions—"Flowering Plants," by James Britten, F L S, "Grasses," by W Hutchinson, "Fishes," by the Rev H C Macpherson, and "Mammalia," by the Rev H C Macpherson

THE SOCIETY FOR PROMOTING CHRISTIAN KNOWLEDGE has nearly ready for publication — "Star Atlas," gives all the stars from 1 to 6.5 magnitude between the North Pole and 34° south declination and all nebulae and star clusters which are visible in telescopes of moderate powers, translated and adapted from the German of Dr Klein, by the Rev E McClure, M A, new edition brought up to date, with eighteen charts and eighty pages illustrative letterpress "Vegetable Wasps and Plant Worms," by M C Cooke, LL D, illustrated "Our Secret Friends and Foes," by Prof Frankland, F R S

MESSRS LONGMANS AND CO are preparing for publication — "The Ruined Cities of Mashonaland" being a Record of Excavations and Explorations, 1891-92," by J Theodore Bent, F R G S., with numerous illustrations of Mashonaland, and of the author's interesting discoveries of the remains of a prehistoric people at the Zimbabwe ruins. An English translation of Willner's "Lehrbuch der Electricitat," in 2 vols, translated and edited by G W de Tunzelmann, B Sc, with 310 illustrations. The English editor has added much new matter, and by some changes of arrangement and mode of presenting the subject has endeavoured to make it a truthful representation of the present state of electrical science "Chemical Lecture Experiments," by G S. Newth

MESSRS LAWRENCE AND BULLEN will publish — "Matriculation Chemistry," by Temple Orme

MESSRS J AND A CHURCHILL promise "Physiology" (Student's Guide Series), by E H Starling, M D, Lond, with 100 illustrations, "A Guide to the Science of Photo-micrography," by Edward C Bousfield, second edition, with 34 woodcuts and frontispiece, "Chemical Technology or, Chemistry in its application to Arts and Manufactures," with which is incorporated "Richardson and Watts' Chemical Technology," edited by Charles Edward Groves, F R S., and William Thorp,

B Sc vol, II Lighting—Sections Stearine, by Mr John McArthur, Candles, by Mr Field, Oils, Oil Fields, Lamps, by Hoverton Redwood, Gas, by Chas Hunt, Electric Lighting, by Prof Garnett, "Commercial Organic Analysis," by Alfred H Allen, F I C, F C S A treatise on the properties, proximate analytical examination, and modes of assaying the various organic chemicals and products employed in the arts, manufactures, medicine, &c, with concise methods for the detection and determination of their impurities, adulterations, and products of decomposition Vol III, Part 2, Organic bases, cyanogen compounds, albuminoids, &c "Wilson's Anatomy," edited by Prof Henry L Clark, eleventh edition, with 26 coloured plates, and 492 woodcuts, "Morris's Anatomy," a treatise by various authors J B Sutton, H Morris, J N Davies Colley, W J Walsham, H St John Brooks, R M Gunn, A Hensman, F Treves, W Anderson, and W H A Jacobson, with more than 500 illustrations, many being coloured, "Ambulance Lectures," to which is added a Nursing Lecture, in accordance with the regulations of the St John Ambulance Association, by John M H Martin, M D, third edition, with 60 engravings, 142 pp, and an English edition of Cominasi Crudeli's well known work on the Climate of Rome

Mr LEWIS'S announcements are — "Various Forms of Hysterical or Functional Paralysis," by H C Charlton Bastian, M D, F R S, "Diseases of the Skin Their Description, Pathology, Diagnosis and Treatment," by H Radcliffe Crocker, M D, F R C P, second edition, with numerous illustrations, "A Text book of Ophthalmology," by Dr Ernest Fuchs, translated from the German by A Duane, M D, in one large octavo volume, with 178 illustrations, "Public Health Laboratory Work," by H R Kenwood, M B, with illustrations, "Hygiene and Public Health," by Lucius C Parkes, M D, third edition, with numerous illustrations, "A Handbook of the Diseases of the Eye and their Treatment," by Henry R Swanzy, M B, F R C S I, fourth edition, illustrated with wood engravings, colour tests, etc "A Pharmacopoeia for Diseases of the Skin," edited by James Startin, third edition, and "The Sanitary Inspector's Handbook and Text book for Students preparing for the Examinations of the Sanitary Institute, London," by Albert Taylor, with illustrations

MESSRS G PHILIP AND SON have in the press — "British New Guinea," a compendium of all the most recent information respecting our Papuan Possession, by J P Thomson, with valuable scientific appendix dealing with the Geology, Fauna, Flora, &c, illustrated with numerous engravings and photographs, and a coloured map, "Christopher Columbus," by Clements R Markham, C B, forming vol VII of the World's Great Explorers and Explorations, with 25 illustrations and numerous coloured maps, "The Development of Africa," a Study in Applied Geography, by Arthur Silva White, illustrated with a set of 14 coloured maps, specially designed by E G Ravenstein, F R G S, second edition, revised to April 1892, "Atlas of Astronomy," a Series of Seventy-two beautifully executed Plates, with Explanatory Notes, by Sir Robert Stawell Ball, F R S, "Astronomy for Every Day Readers," and a Popular Manual of Elementary Astronomy, by B J Hopkins, with numerous illustrations

## SOCIETIES AND ACADEMIES

### PARIS

Academy of Sciences, Sept 12 —M. Duchartre in the chair —On the heat of combustion of glycolic acid, by M Berthelot —Note on several new facts relating to the physiology of epilepsy, by M Brown-Sequard If by epilepsy is understood a group of reflex convulsive movements, it is invariably induced in guinea-pigs by cutting one of the sciatic nerves. If, however, the section has been made in the lower part of the thigh, the convulsive manifestations often are confined to the side of the lesion, and the animal retains consciousness. This is due to the regeneration of the nerve, which takes place rapidly, and which stops the development of the disease, or even cures it altogether. Generally, the greater the number of nerve fibres severed, the stronger is the tendency towards epileptic fits. A set of absolutely decisive facts have shown that a violent attack can be produced which is due to the spinal marrow alone. This epilepsy as displayed in guinea pigs is absolutely equivalent to the idiopathic or cerebral disease in man. Clinical as

well as experimental facts show that epilepsy has no special seat in the brain, but that all parts of the nervous system, central or peripheral, may give rise to it.—The meadows in the dry summer of 1892, by M. A. Chénin.—Absolute positions and proper motions of circumpolar stars, by M. F. Gonessiat.—On a problem of analysis involved in the equations of dynamics, by M. R. Liouville.—On a recurring series of pentagons inscribed in the same general curve of the third order, which can be constructed with the sole help of the straight edge, by M. Paul Serret.—On the calorific distribution of the heat of the sun at the surface of the northern and southern hemispheres of the terrestrial globe, by M. le Comte de Trowelin. It is sometimes thought that the fact of the sun being eight days longer in the northern hemisphere than in the southern, is the principal cause of the inequality of the distribution of heat in the two hemispheres. It can, however, be shown that the quantities of heat received by two symmetrical elements of the earth's surface, or by two caps symmetrical with respect to the earth's centre, are the same during the durations of the earth's journey comprised between two pairs of opposite vectors. Hence the total heat received by the northern hemisphere during spring and summer is equal to that received by the southern hemisphere during autumn and winter. The true cause of the difference of mean annual temperature in the two hemispheres lies in the difference of loss by radiation. By the law of cooling bodies, if two bodies have the same mean temperature, but different extremes, the one with the greatest extremes will lose most heat by radiation. Thus the southern hemisphere, which is nearer the sun in its summer and further away in its winter than the northern, will lose the greater quantity of heat.—Theory of a condenser interposed in the secondary circuit of a transformer, by M. Dénié Korda.—On the thermal variation of the electrical resistance of mercury, by M. Ch. Ed. Guillaume. The relation between temperature and conductivity was determined by comparing the resistance of a mercury standard of about one ohm at different temperatures with another standard maintained at a constant temperature, with a special arrangement to eliminate the resistances of the contacts. The formula deduced was—

$$\rho_t = \rho_0(1 + 0.00088879T + 0.0000010222T^2),$$

and the value of the standard mercury ohm—

$$106 \frac{\text{cm}}{\text{microlitre}} \text{ Hg at } 0^\circ$$

—On a ptomaine obtained from a cultivation of *Micrococcus tetragenus*, by M. A. B. Griffiths. This *Micrococcus*, found associated with human phthisis, gives rise to a ptomaine if cultivated on peptonized gelatine for several days. This ptomaine is a white solid, crystallizing in prismatic needles. It is soluble in water, giving a feeble alkaline reaction. It forms a chlorhydrate, a chloraurate, and a chloroplatinate, all crystallizable. Nessler's reagent gives a green precipitate, tannic acid a brown one, slightly soluble. The formula appears to be  $\text{C}_5\text{H}_8\text{NO}_2$ . It is a poison, and produces death in thirty-six hours. It is undoubtedly the product of the decomposition of the albumin by the microbe.—On echinochrome, a respiratory pigment, by M. A. B. Griffiths. Mr. McMunn discovered a brown pigment in the perivisceral fluid of certain echinoderms in 1883. This was separated by desiccating the fluid and dissolving out by chloroform. The formula of echinochrome is  $\text{C}_{105}\text{H}_{90}\text{N}_{12}\text{FeS}_3\text{O}_{12}$ . It serves a purpose in the body of the echinoderm analogous to that of hæmoglobine in the human body, but is not so highly developed as the latter. The respiratory pigments in the lower animals not only carry oxygen to the tissues, but also retain oxygen in combination till taken up by the cellules. Hence echinochrome, like hæmocyamine, chlorocruorine, and similar bodies, is more stable than hæmoglobine.—Physiology of the pancreas, experimental dissociation of the external and internal secretions of the glands, by M. J. Thiruloix.—Influence of some deleterious gases on the progress of anthrax infection, by MM. A. Charrin and H. Roger.—Contribution towards the aëptic method in hypodermic therapeutics, by M. Barthélémy.—On the construction of a luminous fountain with automatically variable colours, by M. G. Trouvé.

#### BOOKS, PAMPHLETS, and SERIALS RECEIVED

Books.—The Locomotive Engine and its Development. C. E. Sretton (Lockwood).—Universal Atlas, Part 18 (Cassell).—Life Histories of North American Birds. C. Bendire (Washington).—Traité Encyclopédique de

Photographie. C. Fabre. Premier Supplément (Paris, Gauthier-Villars).—VI. Jahresbericht (1890) der Ornithologischen Beobachtungsstationen im Königreiche Sachsen. A. H. Meyer u. F. Helm (Berlin, Friedländer).—Elementary Physiography. R. A. Gregory (Hughes).—Dynamometers and the Measurement of Power. J. J. Flather (New York, Wiley).—A Manual of Veterinary Physiology. Veterinary Captain F. Smith (Baillière).—Australische Reise. R. v. Lendenfeld (Innsbruck, Wagner).—Medical Microscopy. Dr. F. J. Wethered (Lewis).—A Dictionary of Terms used in Medicine, &c. R. D. Hoblyn 12th edition, revised by J. A. P. Price (Whitaker).—The Sea and the Road. C. T. Paske and Dr. G. Affalo (Chapman and Hall).—A Lecture Course in Elementary Chemistry. H. T. Lilley (Simpkin).—Modern Science in Bible Lands, popular edition, revised. Sir J. W. Dawson (Hodder).—A Handy Hook for Brewers. H. E. Wright (Lockwood).—Reports from the Laboratory of the Royal College of Physicians. Edinburgh, vol. iv (Printed).—The Fauna and Flora of Gloucestershire. C. A. Witchell and W. H. Strugnell (Stroud, James).—Observations of Double Stars made at the U. S. Naval Observatory, Part 2, 1890-91. Prof. A. Hall (Washington).—Experimental Evolution. Dr. H. de Varigny (Macmillan).—Oriental (Leadiad). Part 6. W. L. Distant (London).—Paraguay. Dr. F. de B. la Dardye (Philip).—Advanced Building, Construction (Longmans).—Transactions and Proceedings of the New Zealand Institute, 1891, vol. xxiv (Wellington).—Sea sickness, Voyaging for Health. Health Resorts. Dr. T. Dutton 3rd edition (Kampton).—Bulles de savon. C. V. Boys, traduit de l'Anglais par Ch. Ed. Guillaume (Paris, Gauthier-Villars).—Up the Niger. Capt. A. F. Mockler-Ferryman (Philip).—Earth Burial and Cremation. A. G. Cobb (Putnam).—A Vertebrate Fauna of Lakeland. Rev. H. A. Marsherson (Edinburgh, Douglas).—Contributions to Horticultural Literature. W. Paul (Waltham, Cross, Paul).

PAMPHLETS.—Music in its Relation to the Intellect and the Emotions. J. Steiner (Novello).—Sudri Carnot et la Science de l'Energie. M. G. Moutet (Paris, J. Caric).—Appendix to the Catalogue of the Flora of Nebraska. H. J. Webber.—Maryland's Attitude in the Struggle for Canada (Haltmore).—Memorial of J. Lovering (Cambridge, Massachusetts, Wilson).

SERIALS.—Quarterly Journal of Microscopical Science. August (Churhill).—Journal of the Royal Microscopical Society, August (Williams and Norgate).—Transactions of the Academy of Science of St. Louis, vol. v, Nos. 1 and 2 (St. Louis).—Notes from the Leyden Museum, vol. xiv, Nos. 1 and 4 (Leyden, Brill).—Economic Journal, No. 7 (Macmillan).—Journal of Morphology, vol. vi, Nos. 1 and 2 (Boston, Ginn).

## THE SPEECH OF MONKEYS

*The Speech of Monkeys* By R. L. Garner (London Heinemann, 1892)

IT is somewhat unfortunate, and is certainly not a little embarrassing to the critic who desires to take Mr Garner seriously, that he has chosen to present to the world "this first contribution to science on the subject" of the speech of monkeys in the form of popular and chatty anecdotes, with reflections thereon suitable for the delectation of elderly spinsters. This is the style of writing to which we refer, and of which the book before us largely consists.

"I shall long remember how this dear little monk (Pedro the Capuchin) would cuddle up under my chin, and try so hard to make me understand some sad story which seemed to be the burden of his life. I have frequently been entertained by a like speech from little Dodo, who was the Juliet of the Simian tribe. She belonged to the same species as the others, but her oratory was of a type far superior to that of any other of its kind that I have ever heard. At almost any hour of the day, at the approach of her keeper she would stand upright and deliver to him the most touching and impassioned address. The sounds which she used, and the gestures with which she accented them, as far as I could determine, were the same as those used by Dago and Pedro in their remarks to me as above described, except that Dodo delivered her lines in a much more impressive manner than either of the others. I have not been able up to this time to translate these sounds literally, but their import cannot be misunderstood. My belief is that her speech was a complaint against the inmates of the cage, and that she was begging her keeper not to leave her alone in that great iron prison with all those big, bad monkeys who were so cruel to her."

This is the anecdotal style, the heading of the chapter in which Dodo is introduced running thus: "Dago talks about the Weather—Tells Me of His Troubles—Dodo in the 'Balcony Scene,' &c. It is not easy, we repeat, to deal with this kind of thing in a spirit of serious criticism. And then we have passages of which the following is a sample—

"I assert that all mammals reason by the same means and to the same ends, but not to the same degree. The reason which controls the conduct of a man is just the same in kind as that which prompts the ape. That same faculty which guided man to tame the winds of commerce, taught the nautilus to lift its tentacles and embrace the passing breeze. That psychic spark which dimly glows in the animal bursts into a blaze of effulgence in man. The one differs from the other just as a single ray of sunlight differs from the glaring light of noon. If man could disabuse his mind of that contempt for things below his plane of life, and hush the siren voice of self-conceit, his better senses might be touched by the eloquence of truth. But while the vassals of his empty pride control his mind, the plainest facts appeal to him in vain, and all the cogency of proof is lost. He is unwilling to forego that vain belief that he is Nature's idol, and that he is a duplicate of Deity. Held in check by the strong reins of theology and tradition"—and so forth for another page, and a half.

These be the reflections suitable for the delectation of elderly spinsters. We must excuse ourselves from criticising Mr Garner's remarks on reason in animals, for there is no evidence in his book that he has, by a

careful training in psychology, earned for himself the right of expressing a scientific opinion on this difficult question.

And yet Mr Garner is at work upon an interesting and important problem in the elucidation of which scientific results will be of great value, and he is working on the right lines, namely, those of experiment and observation in close contact with phenomena. It is worth while therefore, to dig out from his volume the few results of scientific value he has at present reached, to endeavour to set them in their true light, and to encourage him in the further prosecution of his labours.

It is well known to all observers that animals emit sounds expressive of their emotional states, and that these sounds convey, and are often apparently intended to convey, in intimation to their fellow creatures of such emotional states. No one who has watched a dog growling, a cat swearing, or a lamb bleating, can question this elementary fact. The present writer has lately been observing and making experiments with young chicks. Towards the close of the first week there were at least five well-distinguished sounds: the soft "cheep" of contentment, the more excited note of unusual satisfaction, the complaining "weep-weep" of slight discomfort, the sharper cry when they were caught up, for example, by a strange hand, and, quite distinct from all the rest, the danger "churr." There can be little doubt that these several sounds, as emitted by one of the chicks, were of suggestive value to its little brothers and sisters. And they were quite spontaneous and not the result of imitation, for the chicks had never seen any of their kind. Had these chicks been reared in the ordinary way, and not as experimental orphans, their hen mother would no doubt have given opportunity for observing that by certain sounds she could call her brood's attention to things good to eat. And there can be little doubt that a dog can call its companion's attention to something worrisome, though whether there are differentiations, e.g., for cat and rat, we cannot say. We have ourselves been unable to detect such differences in our own dogs.

It is thus a matter of familiar observation that animals emit sounds which are of suggestive value, and that these sounds are in some cases suggestive of emotional states, and in others of external objects. It is to such sounds as emitted by monkeys that Mr Garner has mainly directed his attention. Let us give in his own words some of his results—

"Standing near the cage of a little Capuchin, I imitated a sound which I had translated 'milk,' but from many tests I concluded it meant 'food,' which opinion has been somewhat modified by many later experiments which led me to believe that he uses it in a still wider sense. It is difficult to find any formula of human speech equivalent to it. While the Capuchin uses it relating to food and sometimes to drink, I was unable to detect any difference in the sounds. He also seemed to connect the same sound to every kindly office done him, and to use it as a kind of 'shibboleth.' More recently, however, I have detected in the sound slight changes of inflection under different conditions, until I am now led to believe that the meaning of the word depends somewhat, if not wholly, on its modulation."

Again—

"I approached the cage [of another Capuchin], and uttered the sound which I have described and translated

'drink' My first effort caught his attention and caused him to turn and look at me, he then arose and answered me with the same word, and came at once to the front of the cage. He looked at me as if in doubt, and I repeated the word, he responded with the same, and turned to a small pan in his cage which he took up and placed near the door, through which the keeper usually passed his food, returned to me, and uttered the word again. I asked the keeper for some milk, which he did not have, but brought me some water instead. I allowed the monkey to dip his hand into the glass, and he would then lick the water from his fingers and reach again. I kept the glass out of reach of his hand, and he would repeat the sound earnestly, and look at me beseechingly, as if to say, 'Please give me some more.' I was thus convinced that the word which I had translated 'milk,' must also mean 'water,' and from this and other tests I at last determined that it meant 'drink' in its broad sense, and possibly 'thirst.' It evidently expressed his desire for something with which to allay his thirst. The sound is very difficult to imitate, and quite impossible to write exactly."

We submit that these passages seem to indicate that Mr Garner has not yet, in this matter, reached results which have much definiteness and precision. It would seem that the Capuchin emits sounds which are mainly expressive of a craving for something, and perhaps vaguely indicate that this something is water or other drink, though with regard to this objective implication we must remember that one of the capuchins "seemed to connect this sound to every kindly office done him."

This is one of the nine words or sounds belonging to Capuchins. Another is the sound which Mr Garner has translated "food." Of it he says—

"I observed that this sound seemed to be a salutation or peace making term with them, which I attributed to the fact that food was the central thought of every monkey's life, and that consequently that word would naturally be the most important of his whole speech."

Another sound which was emitted by a monkey when a storm was going on, and which, when reproduced by the phonograph, made the little fellow look out of window, Mr Garner translated "weather," or thought that it "in some way alluded to the state of the weather." But he does not seem quite clear about it.

"I am not sure," he says, "how far it may be relied upon as a separate word. It was so closely connected to the speech of discontent or pain, that I have not been able since to separate the sounds, and I finally abandoned it as a separate word, but reviewing my work, and recalling the peculiar conduct of this monkey and the conditions attending it, I believe it is safe to say that he had in mind the state of the weather."

Three other sounds are plainly emotional in their nature—(1) an alarm sound, used under stress of great fear, high in pitch, shrill and piercing, (2) a sound written thus "e-c-g-k" expressive of apprehension, and (3) a sound which is like a guttural whisper "c-h-i" expressive of the approach of something which the monkey does not fear.

Such are some of the sounds which Mr Garner misnames (as we think) the "speech" of monkeys, and concerning which he exclaims—

"Standing on this frail bridge of speech, I see into that broad field of life and thought which lies beyond the confines of our care, and into which, through the gates that I have now unlocked, may soon be borne the

sunshine of human intellect. What prophet now can foretell the relations which may yet obtain between the human race and those inferior forms which fill some place in the design, and execute some function in the economy of nature?"

This, however, is one of those reflections which savour of the prattle of the parlour tea-table rather than the sober discussion of the study. We should rather say that Mr Garner's investigations, if followed up in a spirit of critical accuracy, give promise of enabling him to extend our knowledge of the sounds emitted by monkeys—sounds which, we gather from his descriptions, are mainly, if not entirely, of emotional origin, but which may perhaps carry with them a more or less definite objective import. We are of opinion that such extension of our knowledge of these emotional or other sounds may prove a definite and valuable contribution to science, and we therefore heartily wish Mr Garner all success in the prosecution of his inquiry.

C. L. M.

#### BEES-KEEPING.

*Bees for Pleasure and Profit.* By G. Gordon Samson (London: Crosby Lockwood and Son, 1892.)

"HOW doth the little busy bee, &c." asked Dr Watts a hundred and fifty years ago. So long as straw skeps predominated, the problem was insoluble. The bees improved each shining hour in perfunctory fashion, building crooked combs, confusing brood with honey, exhausting their republic with superfluous swarms, dying finally in the smoke-reek of an old pair of corduroys, enriched for malarious exhalation by more than one generation of bucolic wearers. With frame hives came an Earthly Providence to answer the pious query, to control the economy of the hive, to prescribe the number of drones, multiply or restrict the queens, straighten out the combs, combine defective stocks into a single opulent society, disintegrate an overgrown community into new and independent nuclei, supplement the tardy growth of brood or honey, increase fourfold the productiveness of every hive. It is an adept in Providential operations that Mr Samson writes. He renounces scientific erudition, and his allusion to "powerful microscopes," his reliance on "wonderful provisions of Nature," his belief that by confining their visits to one kind of flower in a single journey the bees prevent the hybridization of species, show his disclaimer to be correct, but apian science was brought up to date last year in Mr Cowan's admirable book (*NATURE*, vol. 43, p. 578), leaving room for just such a practical treatise on manipulation and management as Mr Samson is competent to give.

No repetition can exhaust the interest attaching to the strange life-history of the hive bees. While the solitary bees are created male and female, there appears in the gregarious bees a third sex, the workers or neuters (not *neutrals*, as Mr Samson calls them), having rudimentary ovaries and spermatheca, incapable of laying eggs, with the ovipositor modified into a sting, themselves, in queenless hives, sometimes developed into more advanced yet still imperfect females, known as fertile workers, and producing only drones. In ordinary cases a single queen is the mother of the entire hive, bearing drone eggs only in her virgin state, fecundated once for all by a solitary nuptial act for the production of more

than half a million of offspring. During twenty-one days as egg, larva, pupa, the infant bee resides in the comb, fed by its older sisters on a paste of brood-food or chyle, to which in the case of workers honey is added after the first three days. For a week after emergence the young bee remains at home in order to secrete wax, which is detached from the wax pockets by others; it is then promoted to the office of nurse, for a fortnight or three weeks afterwards it gathers honey, spends its maturity in the difficult work of comb-building, dies at the end of six or seven weeks, unless winter hibernation arrests its labour and prolongs its life. The moral of its unique biography has been pointed by many writers; the social lesson of its communistic orderliness, the industrial ideal flowing from its co-operative toil and profit, the political example impressed by the curious completeness with which, at once a red republican and an ardent cavalier, it combines extremest democratic sturdiness with devoted personal loyalty.

The common hive bee, as distinguished from the Bumble, Carpenter, Mason, and other bees, belongs to the genus *Apis*, of which one species only, *A. mellifica*, is indigenous to Britain. During the last few years the Ligurian, Carniolan, and Syrian bees have been largely introduced, from amongst which the cross known as Syrio-Carniolan bears the palm for fecundity, docility, honey-gathering, and hardiness through the winter. With a swarm of these and a ten-frame hive the tyro may begin bee-keeping. In manipulating he must not wear gloves; they make the fingers clumsy, and the sting, painful at first, causes diminishing inconvenience on each successive infliction, till the system is inoculated by the acid, and the sting is harmless. In creating their new home the bees require assistance; one or two frames of brood-comb from the parent hive, with a limited number of drone cells, must be inserted. As the frames fill, the master, utilizing the fact that honey is always stored above the brood, places "supers" over the frames, removing them as fast as they are filled, while the full-charged combs from below are placed in an extractor and the liquid honey is withdrawn. As much as 100 pounds of honey have sometimes been thus obtained in one season from a single hive. The honey harvest begins with the blooming fruit trees in early spring, and slackens after the lime trees fade, but in heather districts a rich autumn store is raised, and Scottish bee-keepers, having reaped the early crop from bean and clover, send their hives by rail or boat to a considerable distance, to be placed upon the heath-clad moors in early August. When an unfavourable winter has depopulated the hives, it is possible to build up one strong colony out of two or more weak stocks, retaining only the youngest and most prolific queen. The bees will resent the coalition, and a general fight will impend, but if sprinkled with thin syrup and with flour their power of discerning Trojan from Tyrian is cancelled by the identity of appearance and of scent.

"Just so the prudent husbandman, that sees  
The idle tumult of his factious bees,  
Powers them o'er, till none discern his foes,  
And all themselves in meal and friendship lose.  
The insect kingdom straight begins to thrive,  
And all work honey for the common hive."

Mr. Samson does well to press the economic value of bees not only as honey-makers, but as fruit-setters. In

cold sunless springs their agency is essential to the fertilization of the bloom, in districts adjoining a large apiary the fruit trees are invariably laden with heavy crops, deteriorating as we remove further from its neighbourhood, and instances are well authenticated from the older counties in which a general destruction of bees by a long and variable winter has been followed by the loss of the apple crop. Both fruit and honey are at present for the most part imported from abroad, if fruit is to be largely cultivated in the small holdings of the future, it must be sustained and enriched by bee-keeping.

In this, as in other industries, there are occasional difficulties baffling to all but experts. Queens will refuse to be reared, supers will remain unhilled, stocks will need stimulation in the spring and building up in early winter, foul brood, deadliest of bee maladies, will infect the hive. In all such complications and for many more Mr. Samson offers full and clear instruction. Portable in form and cheap of cost, his book should form part, along with "smoker," bee veil, queen cage, "driving irons," and "doubling box," of every bee-keeper's equipment.

W. TUCKWELL.

#### A NEW COURSE OF CHEMICAL INSTRUCTION

*A New Course of Experimental Chemistry, with Key*

By John Castell-Evans, F.I.C. (London: Thomas Murby.)

THE basis of the course of instruction here put forward consists in making the student perform an experiment with a definite object in view. The result of the experiment is carefully withheld, and must be discovered by the student himself. In this way he is led to acquire knowledge by his own exertions, and theoretically at least such a method has more to recommend it than any other. In practice, however, the time required to rigorously carry out this system is no doubt an obstacle to its general adoption.

If with the author we lay down the law that "the student must not be allowed to use any chemical name or term until he has discovered for himself the thing or process represented by it," to acquire but a moderate knowledge of the chemistry of to-day appears well-nigh an impossibility. It was thus a matter of interest to see how a work based on this system could be comprised within reasonable limits of space. The author, however, does not seem to intend the above restriction to be literally enforced. To go no further than the first lesson, we find the student employing the ordinary chemicals, phosphorus, ammonium nitrite, potassium chlorate, &c., things which he makes no attempt to discover, only in the case of the more important processes and substances usually met with in a chemical course is any such attempt made.

The book consists of two parts. The first part contains a series of experiments and problems, the latter being set upon a course of lectures which are intended to be given concurrently with the laboratory instruction, and which deal more especially with the physical aspect of the subject. Outlines of these lectures, results of the experiments, and full solutions of the problems are to be found in the Key, which may be obtained separately or bound up with the

two parts. The experiments start off with the commonly occurring phenomena of combustion, and lead up to the laws of chemical combination, the determination of chemical equivalents, vapour densities, &c.

Part II consists of qualitative and quantitative analysis taken together, no attempt being made to separate the two. The results of the experiments are here carefully withheld from the student, and are given in the Key. A useful table for the detection of the positive radicals is published separately, and may be used in connection with this part.

The book can be recommended as a trustworthy one, and, apart from the novelty of the system adopted, as a storehouse of knowledge useful to the chemist, it will be appreciated by many a teacher.

The problems are actual examples met with in the laboratory, and appear to be free from the artificial exercises so common in text books. It is also noteworthy that they, as well as the lectures, are concerned to a considerable extent with the energy changes as well as with the material changes which constitute chemical phenomena.

In glancing at the tables of physical constants to be found as answers in the Key, it is frequently noticeable that these magnitudes are given to an accuracy which is altogether fictitious. For example, to express heats of vaporization or absorption coefficients to one part in thousands of millions, or to give a boiling point such as that of bromine to one thousandth of a degree Fahrenheit, tends to create an erroneous idea of the accuracy with which such determinations can be made. In one or two instances the information is not quite up to date. Hydrofluoric acid, for instance, is still formulated  $\text{H}_2\text{F}_2$ , and Bunsen's values for the absorption coefficients of hydrogen and oxygen are still given, although they have been superseded by the observations of Winkler and Timoféef. Van der Waals's work might have been included in the otherwise serviceable account of the kinetic theory of gases, and it is somewhat unfortunate that the author insists upon the narrow view that specific gravity has no other meaning than that which is perhaps more correctly attributed to relative density.

The printing and the woodcuts are hardly up to the standard usually attained in books of this kind.

J W R

#### OUR BOOK SHELF

*Die Pflanze in ihren Beziehungen zum Eisen.* Von Dr. Hans Molisch. Iron in its Relations to Plant-life. 8vo, 119 pages, with one coloured plate. (Jena: Gustav Fischer, 1892.)

AN interesting essay on the presence, function, and form of iron in plants, embodying the results of previous investigators and of the author's experiments and researches extending over several years. Though the outcome of much labour, Dr. Molisch regards it as preliminary to more extended inquiries, and the whole subject as being yet in its infancy. He discusses the determination of the presence in the vegetable cell of iron in loose combinations and in dense combinations, or what he terms the masked condition. He then describes the occurrence and distribution of iron in plants in loose and dense combinations, and enters somewhat fully into the description of a new method he claims to have discovered

for proving the existence of iron in the masked condition, even when it is present only in infinitesimally small quantities. This is done by soaking the objects one or more days or weeks in saturated aqueous liquor potassæ, and then, after quickly washing them in pure water, subjecting them to the usual reagents. He further claims to have proved that iron is not one of the constituents of chlorophyll. There is also a short chapter on healing vegetable chlorosis by the use of chloride of iron, sulphate of iron, and other salts of iron. W B H

*Up the Niger.* By Captain A. F. Mockler-Ferryman. (London: George Philip and Son, 1892.)

SEVERAL years ago complaints were made about the conduct of various British subjects in the territories placed under the Royal Niger Company. The British Government accordingly sent Major Claude Macdonald to inquire into the matter. He was accompanied by Captain Mockler-Ferryman, who in the present volume gives a full account of the proceedings of the Mission. During the entire journey, which extended over more than 3000 miles, nothing "of a blood-curdling nature" occurred, so that any one who is attracted to books of travel mainly by the chance of finding them full of sensational narratives, need not trouble himself with Captain Mockler-Ferryman's pages. On the other hand, those who like to read about remote regions and their native inhabitants, will find in this book much to interest them. The author is an accurate observer, and notes in a clear and unpretending style the facts by which his attention has been most strongly attracted. His descriptions of the native tribes of the Niger country, so far as he himself observed them, are particularly good, and will not only please the general reader, but be of service to ethnologists and anthropologists. A capital chapter on music and musical instruments, prepared from materials collected by the members of the mission, is contributed by Captain C. R. Day, and the value of the volume as a whole is much increased by a map and illustrations.

#### LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

#### Density of Nitrogen

I AM much puzzled by some recent results as to the density of nitrogen, and shall be obliged if any of your chemical readers can offer suggestions as to the cause. According to two methods of preparation I obtain quite distinct values. The relative difference, amounting to about 1000 part, is small in itself, but it lies entirely outside the errors of experiment, and can only be attributed to a variation in the character of the gas.

In the first method the oxygen of atmospheric air is removed in the ordinary way by metallic copper, itself reduced by hydrogen from the oxide. The air, freed from  $\text{CO}_2$  by potash, gives up its oxygen to copper heated in hard glass over a large Bunsen, and then passes over about a foot of red hot copper in a furnace. This tube was used merely as an indicator, and the copper in it remained bright throughout. The gas then passed through a wash bottle containing sulphuric acid, thence again through the furnace over copper oxide, and finally over sulphuric acid, potash, and phosphoric anhydride.

In the second method of preparation, suggested to me by Prof. Ramsay, everything remained unchanged, except that the first tube of hot copper was replaced by a wash-bottle containing liquid ammonia, through which the air was allowed to bubble. The ammonia method is very convenient, but the nitrogen obtained by means of it was 1000 part lighter than the nitrogen of the first method. The question is, to what is the discrepancy due?

The first nitrogen would be too heavy, if it contained residual oxygen. But on this hypothesis something like 1 per cent would be required. I could detect none whatever by means of alkaline pyrogallate. It may be remarked the density of this nitrogen agrees closely with that recently obtained by Leduc, using the same method of preparation.

On the other hand, can the ammonia-made nitrogen be too light from the presence of impurity? There are not many gases lighter than nitrogen and the absence of hydrogen, ammonia, and water seems to be fully secured. On the whole it seemed the more probable supposition that the impurity was hydrogen, which in this degree of dilution escaped the action of the copper oxide. But a special experiment appears to exclude this explanation.

Into nitrogen prepared by the first method, but before its passage into the furnace tubes, one or two thousandths by volume of hydrogen were introduced. To effect this in a uniform manner the gas was made to bubble through a small hydrogen generator, which could be set in action under its own electromotive force by closing an external contact. The rate of hydrogen production was determined by a suitable galvanometer enclosed in the circuit. But the introduction of hydrogen had not the smallest effect upon the density, showing that the copper oxide was capable of performing the part desired of it.

Is it possible that the difference is independent of impurity, the nitrogen itself being to some extent in a different (dissociated) state?

I ought to have mentioned that during the fillings of the globe, the rate of passage of gas was very uniform, and about  $\frac{1}{2}$  litre per hour.

KAYLEIGH

Terling Place, Witham, September 24

#### Recent Spectroscopic Determinations

In the September number of the *Philosophical Magazine* Mr. Michelson has published determinations, by a most interesting method, of very close double and multiple lines. In any attempt to interpret his results, it is necessary to bear in mind the profound modifications which the internal motions of a gas—the rectilinear motions of the molecules between their encounters, as well as the motions going on within each molecule—had undergone within the Geissler's tubes upon which he experimented.

In a gas under ordinary circumstances the rectilinear journeys of the molecules take place indifferently in all directions, and where this is the case it follows from the well known relation between the surface of a sphere and that of its circumscribing cylinder, that the effect of the velocities which happen to lie between  $v$  and  $v + \delta v$  is to substitute for each line of the spectrum of the gas a band of uniform intensity and without nebulous edges, the width of which can be calculated. This width, for example, is .04 of an Angstrom or Rowland unit (the tentheth metre), in the yellow part of the spectrum and for velocities of the molecules which lie in the neighbourhood of two kilometres per second, which is about the average velocity of molecules of hydrogen at atmospheric temperatures. Hence with all the velocities that prevail among the molecules, the effect of the rectilinear motions under ordinary circumstances is that each line will be symmetrically widened and rendered nebulous. To this effect Mr. Michelson calls attention.

But in the residual gas of a Geissler's tube through which electricity is passing, the case is altogether different. Here the rectilinear motions of the molecules are not alike in all directions, but preponderate in some state of things which must at least double the lines, and may introduce greater complications.

Moreover, different lines may be differently affected, since the behaviour of the gas varies according to its position between the electrodes, as is evidenced by the observed differences in the form and colouring of the striæ, &c., in the several parts of a Geissler's tube.

We must also be on our guard in another respect, when we attempt to interpret the results, since the distribution of the heat energy of a gas between the rectilinear motions of its molecules and the motions within the molecules, which in the case of ordinary gas is a fixed ratio, is certainly largely departed from in gas through which electricity is passing. Until the laws of the new distribution are understood, the temperature of the gas, judged of by its behaviour to neighbouring bodies, will give us little information.

It is to such events as are referred to above, or others which

like them may arise from the special circumstances under which the vapour of sodium was in Mr. Michelson's experiments, that we must apparently turn for an explanation of the doubling of the constituents of the principal pair of sodium lines which he has detected, since he found that "the width of the lines, their distances apart, and their relative intensities vary rapidly with changes in temperature and pressure."

The method of investigation which Mr. Michelson has so successfully applied appears to be by far the most searching means yet discovered of experimentally investigating the intricate and obscure phenomena which present themselves in Geissler's tubes, and we seem justified in hoping for great results from it.

G. JOHNSTONE STONEY

9, Palmerston Park, Dublin, September 22

#### Printing Mathematical Symbols

EVERYONE who has had to correct printers' proofs of mathematical formula must be painfully alive to the pitfalls into which the non-mathematical compositor continually blunders. To such as know the extreme difficulty of getting such formulae properly set up, there have doubtless occurred from time to time suggestions for such simplifications of notation as shall render the composition less liable to derangement. One most sensible step of the kind I allude to is the introduction by Sir G. Stokes of the solidus notation for quotients, whereby

$$\frac{dy}{dx} \text{ is now written } dy/dx$$

The immediate purpose of this letter is not to propound any wholesale scheme of reform, but to advocate one other simple step, and to induce some of my *confidés* to give the world their own suggestions.

Exponentials are a continual stumbling-block to the compositor, and to the printer's reader, who, when he comes to an expression like

$$Ae^{-ax},$$

does his best to make it look a little straighter and turns it into

$$Ae - ax,$$

or into

$$\Lambda e - ax,$$

or perhaps worse.

The reform I advocate is to write the thing as follows —

$$Ae^{x[-ax]},$$

the square brackets being possibly omitted in all cases when their omission would occasion no confusion. One gain in this notation is the reduction of the whole of the symbols to one level, so not breaking the line of type.

Another useful reform, though one on which I fear the probability of agreement is less likely, is the use of the Continental notation for inverse trigonometrical functions, writing, for example,

$$\arctan x,$$

instead of

$$\tan^{-1} x$$

for the angle whose tangent is  $x$ . Our notation is not only liable to continual misprinting, but is very confusing to Continental readers, who again and again read the latter expression as meaning

$$(\tan x)^{-1}, \text{ or } \cotan x$$

I have even seen it reprinted in a German technical journal as

$$\tan - 1 x$$

SILVANUS P. THOMPSON

Technical College, Finsbury, September 22

#### A so-called Thunderbolt

DURING a short storm in Liverpool this summer, I noticed one flash as peculiarly sharp and noisy, and subsequently in the correct bearing from my house the ground was reported as having been struck by a thunderbolt. I examined the place, which was on the greensward of a lake, where the ground was penetrated by a number of fairly clean cut almost vertical holes down which a walking-stick could be thrust. People sheltering near the lake reported a ball of fire and a great splash up of the

water. The odd circumstance about the damage was that it occurred on a simple grass slope, about half way between a tall boat house on the one side and a drinking fountain standing on more elevated ground on the other. Small trees also were in the neighbourhood, and there was no apparent cause why the flash should have selected this particular spot, though indeed it was not within any of the ordinarily accepted "areas of protection." A gentleman—Mr Hewitt—proposed digging for the meteor, and although fairly convinced that it was nothing but an ordinary flash, we thought it just possible that an accidental meteorite might have fallen during the thunderstorm, in which event a flash down the rarefied air of its trail would be a natural consequence. It may be just possible that the popular belief in thunderbolts has some such foundation.

At any rate the excavation was made, with the result of proving that it was an ordinary flash and that the lightning made use of a surface drain pipe, about four feet deep, to get at the water of the lake.

I enclose Mr Hewitt's report

OLIVER J. LODGE

DURING a thunderstorm on the afternoon of Sunday, July 3, 1892, what is described as a "ball of fire" was seen by several persons to descend to the ground, near the south end of the lake in Sifton Park, and immediately afterwards a column of water, about sixty feet high, was shot up from the lake. On examining the spot where the ball of fire was seen to descend, several clean cut holes were observed, and a sod was also found at a little distance from the spot.

A few days afterwards an excavation was carefully made. The sod being removed, the holes were traced down to a surface drain pipe four feet below the surface. At this drain the holes terminated, and the pipe was found shattered. The important holes were found to be six, the largest being seven inches in diameter, the others about two inches. No meteoric matter was found, but it seems curious that this effect was brought about by a flash of lightning only in an open space of sloping grass, when there were trees and houses close by.

#### Peripatus Re-discovered in Jamaica

MRS E. M. SWAINSON has been so fortunate as to find on Beacon Hill, near Bath, three specimens of *Peripatus*, which she has sent to the Institute of Jamaica. The species is doubtless identical with that found by Goode many years ago at the other end of the island. Of the two specimens which we have studied, one has 36 pairs of legs, and is dark pinkish-brown, with the ends of the antennæ pure white, in striking contrast, the other is smaller and darker, without white ends to the antennæ, and with only 29 pairs of legs. The third example, which we have still alive, is larger, but dark in colour. Full details will be given elsewhere later on, and it may suffice for the present to state that the species is very closely allied to *P. Edwardsi* from Venezuela, as described by Sedgwick, but differs in the greater number of legs and the white tipped antennæ of certain individuals (probably the females), in the only slightly curved (not hooked) claws, in the differentiation of the papillæ into two distinct kinds on the dorsal surface, and apparently in other minor matters. There is no dark dorsal line. The genital orifice is between the penultimate pair of legs, and the jaws are almost precisely as in *Edwardsi*. The Jamaican species being evidently new, it is proposed to call it *Peripatus jamaicensis*.

#### Reflection on Valley Fog

A LETTER from an observer at the Lick Observatory appeared in NATURE on August 25, reporting the reflection of mountains in a valley fog. I was therefore much interested to note the following in the *Yorkshire Herald* of September 7—

"SIR,—Possibly it may interest your readers to hear of a natural phenomenon I noticed this morning before 6 a.m. Overlooking, from Leyburn, the valley of Wensleydale, it appeared as though more than half of the dale was filled with water, like a great lake with rising hills on either side, and these hill-sides, above the level of the (apparent) flood, were distinctly reflected in it. The sun was shining brightly at the time, but almost immediately the mist began to disperse, and the mirage faded away. What struck me as unusual was the

extraordinary distinctness of the reflection. Yours, AN EARLY RISKER. September 5, 1892."

In both cases the reflecting film seems to have been near its vanishing point. J. EDMUND CLARK

#### Impure Water in Bread

SOME accurate answers to the following questions would be desirable, in view of public health.

(1) What bacilli—if any—can survive in the amount and duration of the heat of baking in the interior of unfermented bread?

(2) What is the further effect of the carbonic acid of fermentation?

(3) What is the effect of the water being highly carbonated without fermentation, as in aerated bread?

W. M. I. P.

#### The Comets of Brorsen (1846 VII) and Brooks (1892 "d")

THE elements of Brooks's comet "1892 d," as computed by Herberich from four observations made between August 31 and September 5, bear a strong resemblance to those of Brorsen's comet of 1846, calculated by Oudemans, the figures being—

	Comet Brorsen (1846 VII)	Comet Brooks (1892 "d")
$\Gamma$	1846 June 5 479	1892 Dec 19 727
$\omega$	260 12 50	269 24 27
$\delta$	261 53 12	261 2 55
$\tau$	29 18 17	27 57 8
Log $q$	9.50185	9.84455

Brorsen's comet of 1846 was visible to the naked eye on May 14 of that year. It was supposed to be revolving in an elliptical orbit, with a period of about 400 years. W. F. DENNING.

Bristol, September 22

#### NOTE ON THE PROGRESS OF THE DIOPTRIC LENSES AS USED IN LIGHTHOUSE ILLUMINATION

FRESNEL, in 1820, devised and constructed a lens for first order lights of 920 mm radius. It was composed of a plano convex lens, with five refracting prisms concentric with it, and four segments of rings in the corners all gradually decreasing in breadth as they receded from the centre. The separate pieces of which these lenses were made up were cemented together and mounted in metallic frames 30 inches square.

In 1835, the late Mr Alan Stevenson introduced the French apparatus into Great Britain. In doing so he made several improvements, one of which was that he increased the height of the lens from 30 to 39 inches, at the same time diminishing the thickness of the glass. This refractor had eight prisms above and eight prisms below the central lens. From that time Alan Stevenson's lens was almost universally used until a comparatively recent date, when a revolution in the size of lenses took place.

A few years ago inventors were trying to obtain greater power by increasing the diameter and volume of the flames, but Messrs Stevenson pointed out, in 1869, that after a certain point an increase of diameter of the luminary not accompanied by a corresponding increase of the radius of the apparatus was a mistake, as the light became ex-focal and divergent, and that the proper way to secure greater power was to enlarge the diameter of the apparatus. In 1885 they had a lens made to their design of 1330 mm radius, and having a height of 5 feet. This lens, which was named "Hyper-radiant," was tried at the South Foreland against other lenses, and with a large 10-ring gas burner it was found to give a light from one and a half to twice as intense as the ordinary lenses which were pitted against it, with the same large burners in their foci, thus proving conclusively that to get the power out of large burners it was imperatively necessary

to increase the diameter of the apparatus. In 1883 Messrs Stevenson got an offer from Messrs Barbier for a lens of 1840 mm focal distance.

All refracting lenses from the day of Alan Stevenson were cylindrical for fixed lights and plano-convex for revolving lights, and no alteration of any moment has been made in the mode of their construction until 1888, when, instead of making the lenses cylindrical or plano-convex, I proposed to give them a spherical form, that is to say, circular not only in the horizontal but also in the vertical section. This design was carried into practice in the apparatus for one of the Fair Isle Lighthouses. The introduction of the spherical refractor has made practicable the construction of very much larger and consequently more powerful apparatus, and occupying much less space both in the daylight size and diameter of lantern, and, hence, diameter of tower. It has rendered practicable the quadrilateral arrangement with hyper-radiant lenses which have already been erected at Fair Isle, the lenses being cut so as to give two flashes from each side of the quadrilateral. An experimental lens made for Mr Wigham is to be tried in Ireland. It is 2m focal distance, and the spherical refractor is 7 feet 6 inches diameter, and will give one flash from each side of the quadrilateral. M Barbier says that in making this lens he was attempting to give the most powerful flash possible, and he adopted the spherical refractor. In this case, however, the spherical refractor has been carried, in my opinion, rather far, except in the view of economy in keeping the angles of the whole apparatus within reasonable limits, which is only possible (in an apparatus of 4m diameter) by the use of the spherical refractor, and by its being made to subtend a great angle. When I proposed this form I pointed out that there was a loss of efficiency if it subtended more than  $40^\circ$ , now M Barbier has made the spherical portion subtend  $64^\circ$ , or  $24^\circ$  farther, and  $8^\circ$  farther than any spherical refractor yet made. The great amount of light which I experimentally found re-

by the greater divergence which takes place in the spherical refractor, and which would be a small source of loss in a revolving light, but would better illuminate the nearer sea in a fixed arc.

#### *Equiangular Refractor*

To obviate the loss of light at the outer face of the lenses, especially those remote from the focal plane—a

turned from the inner face of the spherical refractor made for Fair Isle, however, shows that up to  $20^\circ$ , and perhaps farther, it is ample to make up for any loss of light caused

loss which stops the refractor being carried with due regard to efficiency farther than  $30^\circ$  to  $40^\circ$  in the cylindrical form, and  $20^\circ$  in the spherical form—it will be found that the most efficient form is a refractor which I proposed, with the inner face of each lens doing equal work with the outer face, or nearly so—and by a careful study of such a refractor it will be found that the locus of the centres of curvature of each refracting lens lies outside the refractor, and at points below the focal plane, and more and more remote from the lens, as the lenses are more and more remote from the focal plane, and that the inner face of the refractor ought, in fact, to be a parabolic curve (Fig 1). This can very closely be approximated to by a circular curve with a suitably chosen centre on the focal line produced, but the centre is so far distant that when the spherical form and the equiangular form are used in combination (Fig 2), the inner face of the equiangular prisms above and below it may, with sufficient accuracy, be made straight and leaning outwards in place of being vertical as in Fresnel's form. By the combination of the spherical refractor and the equiangular, or a refractor of the equiangular form alone, the defect in Fresnel's refractor, namely the loss of light at emergence from the lenses, especially those remote from the focal plane, is avoided, and the refractor may thus be made to subtend an angle which has hitherto been considered inexpedient, with glass of the ordinary

refractive index of 1.53. The equiangular prisms cause less loss of light by absorption and reflection than either the spherical or Fresnel refractors, and also act on the light so that ex-focal light is better dealt with, thereby reducing the divergence.

CHARLES A. STEVENSON

### MODERN DYNAMICAL METHODS

A DYNAMICAL system is said to possess a *given* number of degrees of freedom, when it is capable of assuming the *same* number of independent positions. The position of the system, in any possible configuration, is capable of being determined by a definite number of independent quantities, which are equal to the number of degrees of freedom of the system. These quantities are called the co-ordinates of the system.

When the system possesses *n* degrees of freedom, the motion may be completely determined by expressing in mathematical language a principle which may be conveniently termed the *principle of momentum*. This principle is specified by the following two propositions — (i) *The rate of change of the component of the linear momentum, parallel to an axis, of any dynamical system, is equal to the component, parallel to that axis, of the impressed forces which act upon the system*, (ii) *the rate of change of the component of the angular momentum about any axis, is equal to the moment of the impressed forces about that axis*. Since the motion of the system may be referred to any set of fixed or moving rectangular axes, the above-mentioned dynamical principle furnishes six equations connecting the six co-ordinates, which, when integrated, will determine the latter in terms of the time and the initial circumstances of the motion.

The various ways of expressing this dynamical principle in mathematical language are explained in treatises on dynamics, and a variety of special forms and particular cases are obtained, by means of which the solution of numerous problems can be simplified. For example, Euler's equations, for determining the motion of rotation of a single rigid body about its centre of inertia, is a particular case of the second proposition, whilst Kirchhoff's equations, for determining the motion of a single solid in an infinite liquid, is a special form of both propositions.

When a conservative system possesses seven degrees of freedom, the motion may be completely determined by means of the principle of momentum combined with the principle of energy. The first principle, as we have already shown, furnishes six equations, whilst the second furnishes one, hence, we have a sufficient number of equations for determining the motion.

When a dynamical system possesses more than seven degrees of freedom, the principles of momentum and energy are insufficient to determine the motion, and under these circumstances, the most convenient method to adopt is to use Lagrange's equations, but inasmuch as these equations are double-edged tools, which are apt to cut the fingers of the unwary, their employment requires considerable care.

The kinetic energy of a dynamical system can be expressed in a variety of different forms, but it will only be necessary to mention the following three. In the first form, it is expressed as a homogeneous quadratic function of velocities, which are the time variations of the co-ordinates of the system. This form, which will be denoted by  $T$ , is called the *Lagrangian form*, it is the only one which it is permissible to use when employing Lagrange's equations, and many mistakes have been made by persons who have attempted to use some other form.

In the second form, which is called the *Hamiltonian form*, the kinetic energy is expressed as a homogeneous

quadratic function of the momenta of the system. If  $\theta$  be any co-ordinate, and  $\Theta$  the generalized momentum of type  $\theta$ , it is known that

$$\frac{\partial T}{\partial \theta} = \Theta \quad (1)$$

whence  $\Theta$  is a linear function of the velocities. Hence, if the velocities be eliminated from the Lagrangian expression for the kinetic energy by means of (1), it follows that the latter will be expressible as a homogeneous quadratic function of the momenta  $\Theta$ , which is the Hamiltonian form. We shall denote this form by  $\mathcal{T}$ .

Lagrange's equations are

$$\frac{d}{dt} \left( \frac{\partial T}{\partial \dot{\theta}} \right) - \frac{\partial T}{\partial \theta} = - \frac{\partial V}{\partial \theta} \quad (2)$$

where  $V$  is the potential energy, and if the elimination be performed, we shall obtain

$$\frac{d\Theta}{dt} + \frac{\partial \mathcal{T}}{\partial \theta} = - \frac{\partial V}{\partial \theta} \quad (3)$$

we have also the reciprocal relation

$$\frac{\partial \mathcal{T}}{\partial \Theta} = \dot{\theta} \quad (4)$$

Equations (3) and (4) are Hamilton's equations of motion.

The third form of the expression for the kinetic energy is of special importance in hydrodynamics and other branches of physics. It sometimes happens that a quantity occurs which can be recognized as a momentum, or as a quantity in the nature of a momentum, whilst the velocity corresponding to this momentum is either unknown or would be inconvenient to introduce. This occurs in problems relating to the motion of perforated solids in a liquid, when there is circulation, and is a particular case of Dr Routh's theory of the "Ignorance of Velocities".<sup>1</sup> We therefore require a form of Lagrange's equations in which certain velocities are eliminated, and are replaced by the corresponding momenta.

Let the co-ordinates of the system be divided into two groups,  $\theta$  and  $\chi$ , and let  $\kappa$  denote the generalized momentum corresponding to  $\chi$ . Then

$$\frac{\partial T}{\partial \chi} = \kappa \quad (5)$$

By means of (5) all the velocities  $\chi$  can be eliminated from the expression for the kinetic energy, and it is remarkable, that the result of the elimination does not contain any products of the form  $\kappa \dot{\theta}$ . The expression for  $T$  may accordingly be written

$$T = \mathcal{I} + \mathcal{K} \quad (6)$$

where  $\mathcal{I}$  is a homogeneous quadratic function of the velocities  $\dot{\theta}$ , and  $\mathcal{K}$  is a similar function of the momenta  $\kappa$ .

Equation (6) is therefore a mixed form, which is partly Lagrangian and partly Hamiltonian. We now require the corresponding form of the equations of motion in which all the  $\chi$ 's have been eliminated from Lagrange's equations.

From (1) it follows that the generalized momentum  $\Theta$  is a linear function of the velocities  $\dot{\theta}$ ,  $\chi$ , and if the latter velocities be eliminated by means of (5), it follows that  $\Theta$  is expressible as a linear function of  $\dot{\theta}$ ,  $\kappa$ . Let the portion which is a linear function of the  $\kappa$ 's be denoted by  $\Theta'$ , then it can be shown, that if

$$L = \mathcal{I} + \mathcal{I}(\dot{\theta}) - \mathcal{K} - V \quad (7)$$

the equation of type  $\theta$  is

$$\frac{d}{dt} \left( \frac{\partial L}{\partial \dot{\theta}} \right) - \frac{\partial L}{\partial \theta} = 0 \quad (8)$$

<sup>1</sup> Having regard to the object of the theory, I think the phrase "Ignorance of Velocities" is better than "Ignorance of Co-ordinates."

whilst that of type  $\chi$  is

$$\frac{d\kappa}{dt} - \frac{\partial I}{\partial \chi} = 0 \quad (9)$$

We have also the additional equations

$$0 - \frac{\partial I}{\partial \theta} + \Theta \quad (10)$$

$$\chi - \frac{\partial \chi}{\partial \kappa} - \Sigma \left( \theta \frac{\partial \Theta}{\partial \kappa} \right) \quad (11)$$

Equations (7) to (11) were first given by myself in a paper published in the Proc Camb Phil Soc for 1887, and it will be observed that they include the equations of Lagrange and Hamilton. A form of the modified Lagrangian function, which is equivalent to (7), was given by Dr Routh a few years previously, but it is not of much practical use, owing to the fact that the elimination of the velocities  $\chi$  has not been performed.

It sometimes happens that the co-ordinates of the type  $\chi$  do not enter into the expression for the energy of the system, in which case they are called *ignored co-ordinates*,<sup>1</sup> under these circumstances it follows from (9), that all the momenta  $\kappa$  are absolute currents. A top spinning about its point under the action of gravity is one of the most familiar examples of ignored co-ordinates, and one which illustrates several important dynamical theorems.

When there are ignored co-ordinates, the steady motion of the system, and the stability of the steady motion, can very easily be investigated. For if we suppose that all the co-ordinates  $\theta$  have constant values, (8) reduces to

$$\frac{\partial R}{\partial \theta} + \frac{\partial V}{\partial \theta} = 0$$

There are as many equations of this type as there are co-ordinates  $\theta$ , and an examination of this system of equations will show whether steady motion is possible, and if so, will determine the necessary conditions which the co-ordinates  $\theta$  and the constant momenta  $\kappa$  must satisfy.

It can also be shown that the steady motion will always be stable when  $R + V$  is a minimum (see Proc Camb Phil Soc May 1892).

We have therefore the following simple rule for determining the steady motion of a dynamical system when there are ignored co-ordinates. Eliminate all the velocities corresponding to these co-ordinates from the expression for the kinetic energy of the system, so that the latter is expressed in terms of the velocities  $\theta$  and the momenta  $\kappa$ . Let  $R$  and  $V$  be that portion of the *total* energy which does not depend upon the  $\theta$ 's, then the conditions of steady motion are, that  $R + V$  should be stationary, and the steady motion will be stable provided this quantity is a minimum.

The preceding theorem also enables us to deduce by a very concise method all the results connected with the steady motion of a liquid ellipsoid, which is rotating about a principal axis under the influence of its own attraction. It also enables us to examine the stability of these different cases of steady motion, for disturbances which produce an ellipsoidal displacement.

A. B. HASSER

### THE PASSAGE OF GRANITE ROCK, INTO FERTILE SOIL

HAVING for the last three or four years paid particular attention to the natural formation of soil, I venture to believe that a concise account, or rather

<sup>1</sup> I must confess that I do not like the phrase *speed co-ordinates*, introduced by Prof. J. J. Thomson, for it conveys absolutely no meaning to my mind. I have no sympathy with the attempts, which have occasionally been made, to introduce short words of Teutonic origin into scientific nomenclature, as the words in question appear to me to be singularly deficient in point.

summing up, of the results of my researches, and of the mass of my observations—in one typical direction—may be of interest to the readers of NATURE. As indicated in the heading, the making of soil from granite is the only section of a very large subject which will be briefly considered in this paper.

The agents concerned with the turning of granite (or any other rock) into a fertile soil may be shortly classified as mechanical, chemical, and vital. The first-named produce the largest results in bulk, and the principal mechanical agent with which we have to deal is frost. The second and third classes of forces are extremely important, as it is by their actions that the raw material of plant-food is prepared, though unfortunately poisons also are brought into being through their activity. These last named classes, however, likewise materially aid the action of frost (or, in tropical countries of varying temperatures) in the mechanical separation of rocky matter. To render my descriptions as little confusing as possible I will endeavour, without regard to classification, order, or divisions, to trace the history of a granite soil as I have observed it in many localities in Scotland, from the practically unbroken rock into the condition in which it has been made by nature fit to bear the most luxuriant crops. But first of all I must remind my readers of two or three geological facts about granite. It is a holocrystalline (i.e. wholly crystalline) igneous rock, composed essentially of orthoclase, quartz, and mica. In its most typical condition the last-named mineral is always of the biotite or magnesia-mica species. Besides these essentials we always find (in Scotch granites at least) plagioclase, other species of mica than the essential, apatite as an endomorph, i.e. locked up in the mass of other minerals, and magnetite, and almost invariably, if not always, a little pyrites, and more or less hornblende, &c.

A rough mineralogical analysis of Kemnay granite taken from the lowest working of the well-known quarry in Aberdeenshire gave the following percentages—

Orthoclase felspar	42 00
Quartz	22 00
Biotite-mica	20 00
Plagioclase felspar	9 00
Hornblende	3 25
Muscovite mica	2 00
Magnetite (and Ilmenite)	1 00
Pyrites	0 50
Apatite	0 25
Total	100 00

The first change which comes over granite is the peroxidation of some of the iron always present in its mass. This sets in, and increases to the greatest extent, of course, where air and water can most readily enter. The surface of the rock becomes browned with the hydrated ferric oxide formed, and brown skins, of a deeper colour than the surface generally, coat the walls of the original rock joints. But in the mass of the rock, away from these primary fissures, there are areas which are more permeable than others from the surface, and through these, streaks of ferric oxide—anhydrous first, afterwards hydrated—are produced. Those lines of rust are the beginnings of a new set of joints, which have not yet been properly recognized in geological literature, and which I will here call weather joints to distinguish them from the primary joints of consolidation and rock movements. The first oxidation streaks of the coming weather fissures are invisible to the eye, but can be determined under the microscope. They gradually increase in width above as they extend their lines beneath, and they afford passages through which water can more readily percolate than in the surrounding fresher areas, and as a consequence planes along which frost can more powerfully act. By

the constant multiplying of the weather joints, which are first marked out by oxidation as already indicated, and afterwards made definite and widened from the most exposed rock surface inwards by frost, one of the first steps in soil formation is accomplished. As those fissures are increased the uppermost portion of the rock is separated by them into distinct pieces, which latter are again in their turn broken up by the formation of weather joints in the same way as the original. The great bulk of a soil has been produced in this way.

While the oxidation of the iron, as I have observed, is very likely the first change to set in in every case, it is never left for any lengthened period to promote, by itself alone, the decomposition of the rock. Very soon the work of carbonation is seen to be progressing alongside of it, though at a considerably slower rate. The carbonic acid gas of moist air, dissolved in the penetrating water, attacks the feldspar, the biotite, and the hornblende. The way in which it brings about the decomposition of these minerals is interesting. Certain molecules succumb much more easily to the action of the carbonic acid than others, and the result is that scattered points of weakness from the thorough decomposition of these are brought into being in different parts of the mineral, and those decomposed portions warp round about the other and fresher molecules, as shown in the unaxed diagram, which has been constructed from what I have observed in decomposed feldspar.

The clay of decomposed feldspar has great plastic and warping power. I have observed only 15 per cent of pure clay in a mass hold the 85 per cent of other and different constituents together in a plastic union as if the whole had been pure clay. There are two or three other hitherto unknown facts connected with the natural decay of feldspar which I have ascertained from my re-

Diagram of kaolined feldspar  $\times 260$ . The whole ground mass is kaolin or pure clay. The holes scattered through this are parts of the original feldspar not yet decomposed.

searches. I have noted two processes of decomposition—that which occurs when the carbonic acid is in excess or can obtain free access to the mineral, and that which takes place when either of the opposite conditions prevails. In the first case the feldspar—supposing it to be *orthoclase*—has the molecules of its body which are affected completely broken up into clay, solid secondary or colloid silica, and carbonate of potash. In the second case, where for some reason a sufficient supply of carbonic acid cannot get within “chemical” distance of the feldspar molecules, clay is produced as before—only more slowly—but the potash of the molecule is carried off in two sections, part as a carbonate, and part as a soluble silicate. From the *plagioclase*-feldspar the same conditions produce similar results, except that the soluble silica which would be produced here is of course in combination with sodium. I have found the soluble silica of soils *always* in the form either of silicate of potassium or sodium, and very frequently both of these occur mixed together.

*Biotite*, by the continued action of carbonic acid, oxygen, and water, loses magnesia (taken out as carbonate) and iron (removed either as oxide or carbonate) and be-

comes eventually the white or yellow muscovite variety which undergoes no further chemical change. In biotite, however, the chemical change usually takes place much more uniformly through the mineral body than ever happens in the case of the feldspar.

*Hornblende*, by carbonation, oxidation, and hydration yields lime as carbonate until the whole of that base is taken out, a trace of magnesia as carbonate (the bulk of this base is almost invariably left in the insoluble residue), the chief portion perhaps of its iron as oxide and carbonate, manganese as hydrated oxide, and any trace of sodium and potassium which it may contain as carbonates, or partially when conditions are less favourable as soluble silicates. The residue left after the hornblende has lost the above can generally be determined as some variety of chlorite (hydrated silicate of magnesia, iron, and alumina), which in the course of time by further loss of iron becomes an impure serpentine, and this later on a steatite or magnesia clay, to which the greasy feel of soils is due.

The *pyrites* of the granite rock is slow to change, but it also is eventually acted on, by water and oxygen particularly, the latter combining with its substance here and there to form a sulphate, which has a great mission in the physiology of the soil.

I have said that the *apatite* occurs as an endomorph. It is set free to dissolve slowly without change in ordinary carbonated water when the minerals which hold its microscopic needles in their substance are broken up, mechanically or chemically. The *magnetite* and *ilmenite* grains of the granite rock are only altered with provoking slowness. Their function, however, in the work of the soil is, as far as I can see yet, of no importance. Traces at least of another mineral occur very frequently in granites. This is tourmaline, the history of which in soils I have been investigating for the last half-a-dozen years with some success.

The chemical changes which I have been mentioning begin first on the exposed surfaces of the rock and along the faces of the primary joints. Then oxidation occurs in streaks and bands through the rock mass, and around those areas carbonation is most active. In fact oxidation opens up the rock for further change, chemical as well as mechanical.

Frost is the principal agent of disintegration or mechanical breaking up in this country, but a relatively minute portion of the work is accomplished by heat and cold, the friction of percolating water, changes in the degree of humidity of the atmosphere, the pressure exerted by roots, and so on.

No sooner does a fraction of the surface percentage of the exposed rock portion undergo chemical change than a new element in the making of soil comes into play—that, namely, of organic matter, first living, and then dead and living. We will deal first with the living matter. On the partially decomposed surface of rock, fungal and algal spores (the latter of a lowly type) settle and live and grow in symbiotic union as lichens. There are many different kinds of rock-lichens, but the vegetative physiology of all is identical. The surface of the growth which lies next the stone is engaged in parts, during moist weather at least, in the imbibition of water, with the exceedingly meagre amounts of mineral matters dissolved in it from the surface of the rock. Those absorbing areas of the under surface appear to be also superficial breathing organs, for they certainly excrete carbonic acid gas, which of course will join with the atmospheric carbonic acid in helping the work of decomposition of mineral bodies. And it appears to me—though here I am not certain—that these absorbing areas are less generally found over the quartz of the granite, which is not capable of chemical change, than over the decomposable minerals. The lower absorbing areas of the lichens are in their functional relations common to internal fungal and algal

\* See also in this connection my article on “The Action of Lime on Clay Soils,” *NATURE*, Jan 29, 1890.

members, and the upper surface of the colony is also a common absorbing (and transpiring) tissue, though here it is only the atmosphere gases which are taken in to the interior. There is not the slightest doubt but that the fungal members utilize the nitrogen of the air, there is none in the rock for them to receive, and that the algal members absorb carbonic acid gas from the air taken in, and combine it with the elements of water to make carbonaceous food, for that again is not presented to them from the rock, the lichen growth cannot any more than is the case with higher plants utilize the carbon of the mineral carbonates in the manufacture of carbohydrate or hydrocarbon food.

In reproduction, separate spores of algae and fungi are produced from the lichen, and some of these may germinate above the parent community and unite to form a fresh colony upon the old, or a new colony may be produced from foreign spores. In any case we find generation after generation of lichens forming on the same favourable spot, but succeeding generations are partially parasitic and saprophytic in nature, as is shown by the manner in which their lower absorbing surfaces or prolongations act on the lichen growths beneath them. By and by, when perhaps a score of lichen colonies have formed one above the other—the newer slowly extinguishing the life of the older—a vegetable considerably higher in the scale of being comes forward and caps the last lichen. This is some variety of moss. Spores of moss, carried to the stone surface, germinate there in moisture, and if upon lichens, the moss plantlet develops into the adult. Its rhizoids pierce their way through the substance of the lichens, and many get down to the decomposing stone surface, while some never leave the lichen bodies. The action of the moss rhizoids on living and dead lichens, also, I think, shows that that plant can be a parasite and a saprophyte as well as a normal vegetable feeder, and in this respect, except in its not utilizing the nitrogen of the air, resembles the later lichen growths.

In this way, by the succession of lichens and mosses (and afterwards higher plants), the essential organic element of soils becomes early incorporated with the mechanically and chemically disorganizing rock.

The dead organic matter changes in different ways: first, very slowly and very indifferently, by the action of air and water, and second, rapidly, by the spreading through its mass, where air has free access, of bacteria and other lowly fungi which are saprophytic, but can also assimilate nitrogen from the atmosphere, as is shown by their increasing, and not simply maintaining the original amounts of nitrogen left by their predecessors. By the first method of change the organic matter becomes the tougher former of humus, and humic and other related acids arise from it, by the second the mild, dry, or friable humus is produced and little or no humic acid. A very careful investigation shows that those bacteria which have the power of removing from the dead organic matter the elements of their nutrition give out by the decay (which occurs rapidly) of their bodies when they die the nitrogen and other elements in an active state. The nitrogen of the dead bacteria forms readily nitrate of lime or potash by contact with these bases.

Now to give a short summary here. Oxidation of iron is the first change perceivable in granite, then creation and multiplication of weather joints, and carbonation follows, next humus is formed by lichens, and then higher plants, following this, fungoid germs, capable of assimilating aerial nitrogen, become abundant, finally all the three processes, mechanical, chemical, and organic, go merrily on together and contribute all in their proper shares to the formation of an ever-deepening soil, capable of supporting the luxuriant life of the highest plants. The humic acid which is formed by the inorganic decay of humus has a certain decomposing action, but it gradually changes to carbonic acid, with the action of which, in this

connection, we have already dealt. Well, to apportion the shares of the work done further. By disintegration or mechanical action, the great rough mass of the soil is produced. By oxidation and carbonation, soluble minerals capable of entering the plant are prepared, and insoluble matters like secondary silica, pure clay, and steatite, are brought into being. By the action of living matter, rock decomposition is hastened, and nitrogenous substance is brought into the soil. By the presence and action of dead organic matter, rock decomposition is also forwarded, and a field for aerial nitrogen-assimilating germs is prepared. The table below gives a list of the materials found in the youngest granite soil on which nothing higher than rock-mosses are growing.

Granite minerals in fairly free condition	About 80 per cent
Clay and insoluble secondary silica	About 3 per cent
Soluble silica	Not determinable
Carbonates of potash, soda, lime, magnesia, iron, and phosphate of lime	About 2 per cent
Sulphates of above, except iron	Not determinable
Sulphate of iron	Merest trace
Peroxides of iron and manganese	About 3 per cent
Humus	12 per cent

Total

100 per cent

Later on, as the soil deepens, we find some curious changes proceeding, which I will briefly indicate. Sulphates are now produced in considerable quantities. Wherever iron-containing minerals are brought into contact with organic matter, sulphate of iron tends to form as well as carbonate (humate?), and possibly other compounds, and the pyrites which was slow to change at the beginning now produces sulphate of iron with greater rapidity. The dissolved sulphate of iron coming into contact with the carbonates of the alkalies and alkaline earths liberated from the felspars, hornblende, &c., is already explained, causes a double decomposition. The ferrous sulphate becomes a carbonate, and the carbonates of lime, potash, soda, &c., become sulphates. The iron carbonate, where exposed to air, readily oxidizes to ferric oxide, the chief colouring ingredient of the soil.

Now, in the finished soil, which, it must be remembered, is when produced from granite a loam, we have the following approximate composition, as fairly typical of a good granite soil such as may be found in the valley of the Don in Aberdeenshire—

	Per cent
Insolubles	about 10
Pure clay and steatite	20
Quartz and secondary silica	4
Muscovite	30
Orthoclase	4
Plagioclase	9
Biotite	0.5
Magnetite?	2
Substances capable of transformation	
Hornblende	9
Hematite and limonite (ferric oxides) and manganic oxide	0.5
Pyrites	5
Humus and animal organic matter, fungi, &c.	0.5
Injurious solubles	
Humic acid	0.3
Soluble silicate	0.5
Ferrous sulphate <sup>1</sup>	0.3
Phosphates of lime, magnesia, potash, soda, &c.	0.8
Sulphates of lime, potash, soda, magnesia, &c.	0.3
Non-injurious solubles	
Nitrates of lime, potash, soda, magnesia, &c.	0.1
Carbonates of lime, potash, soda, magnesia, &c.	1 trace
Chlorides of above	3.2
Water and air (mechanically held) in dry summer perhaps about	100.0
Total	

<sup>1</sup> More than 0.1 per cent is injurious.

In conclusion I have to point out, as shown by my investigations commenced four years ago, that farmyard manure laid on to the land is only rendered properly available to the crops by the action of bacteria as indicated above in connection with the natural humus. The inorganic forces have little action upon it, except in producing humic acid and other injurious matters.

The most of the soluble mineral substances in a mature soil, it may also be mentioned, are in the form of sulphate. They originate from the primary minerals as carbonate, but are soon altered, mainly by the ferrous sulphate. The sulphate unfortunately is not the most suitable form in which minerals can be presented to plants for absorption, for the simple reason that, being so stable in chemical union, it causes the loss of too much of the plant's energy in the interior of its body before it can be decomposed. It must be remembered that green plants decompose the compounds which enter their system before they utilize their elements or simpler forms in the elaboration of food.

ALEXANDER JOHNSTONE

Edinburgh, August 5

### THE IMPERIAL INSTITUTE AT ST PETERSBURG<sup>1</sup>

IN November, 1885, some months after the publication of Pasteur's discovery for the treatment of hydrophobia, an officer of the Russian Guards was bitten by a rabid dog. This officer having been sent to Paris to undergo the treatment, his Highness Prince Alexander Petrowitch d'Oldenburg established, at his own expense, a provincial laboratory at St Petersburg, where Pasteur's treatment could be duly carried out. This establishment, however, soon proved to be too small for scientific investigations to be properly carried out therein, and it was decided to build a large laboratory in which researches might be made under the best possible conditions, accordingly the same enlightened nobleman bought a piece of ground of 37,464 square metres in extent, on which the present Institute is built.

The buildings comprise physiological, pathological, chemical, bacteriological, and epizootological sections, with their laboratories, under the direction of such men as Neucki, Winogradsky, and others. There is also a department where Pasteur's treatment is carried out, together with a small hospital for infectious cases. Each section is complete in itself, and all the arrangements are on the newest principles and on a very large scale. The expenses are defrayed partly by the Prince of Oldenburg and partly by public subscription, and the whole Institute compares favourably with any Institute in France or Germany.

The directors of the Institute publish every two or three months a volume embodying the scientific results obtained in the laboratories, and the first two numbers have now been published. As might be expected after what has just been said, their contents are of wide and varied interest. Neucki publishes some chemical researches on the microbe producing inflammation of the mammary glands of milch cows and goats, and his paper will specially interest those who in this country have followed the remarkable researches of Dr E. Klein. Winogradsky gives an account of the various nitrifying organisms discovered by him in the soil of different countries. This author quotes the researches of Prof and Mrs. Frankland, and of Prof Warington, and though to some extent contradictory, Winogradsky's researches agree with those of the English observers in all essential particulars. This paper is certainly the most important which has as yet appeared on this vexed question. The results obtained by Pasteur's treatment in St Petersburg

<sup>1</sup> "Archives de Sciences Biologiques publiées par l'Institut Impérial de Médecine Expérimentale à St Pétersbourg," Vol. 1, No. 1 et 2.

form the subject of a paper by Kraiouchkine, and it may be mentioned that the treatment appears to have been as successful at St Petersburg as in Paris.

The other papers refer to the chemical and physiological effects of tuberculin (Bujwid, Helmin), to the transformation of nutritive media by the bacillus of diphtheria, and to the chemical composition of this micro-organism (Dzierzowski and Rekowski), while Blachstein endeavours to draw a distinction between the bacillus coli communis and the bacillus typhi abdominalis, based on the chemical decompositions produced by these organisms in the media in which they grow. Lastly, Mizerski and L. Neucki give a critical *résumé* of the methods used to estimate the quantity of hydrochloric acid contained in gastric juice.

The researches which form the subjects of these papers are varied enough, and whilst congratulating their authors we may express the hope that the Institute will have a long and prosperous career. Our good wishes must be tinged with regret for ourselves—regret that there should not be a similar Institute in England, and regret also that there should be in this country a class of people who will oppose the establishment of such an Institute until a Bishop or Royal Duke has died of rabies.

M ARMAND RUFFER

### NOTES

LAST week much anxiety was felt as to the health of Sir Richard Owen. On Monday his condition was better, and the improvement, was maintained on Tuesday.

THE herbarium of the British Museum has acquired, by presentation from the widow, the very valuable collection of *Muscineæ*, made by the late Mr George Davies, of Brighton. It comprises upwards of 20,000 specimens of mosses, hepaticæ, and lichens, partly gathered by Mr Davies in Great Britain and on the Continent, partly communicated to him from New Zealand, Samoa, India, the West Indies, and America.

PROF HIERONYMUS has been appointed curator of the Royal Botanical Museum at Berlin.

THE Exhibition of the Photographic Society of Great Britain was opened on Monday at the Gallery of the Royal Society of Painters in Watercolours. It will remain open till November 10.

WE regret to have to record the death of Mr George Croom Robertson. He was fifty years of age, and only lately, in consequence of ill health, resigned the professorship of Mind and Logic at University College, London, to which he was appointed in 1866. Prof Robertson was well known as a brilliant teacher of the subjects to the study of which he devoted his life, and as the editor of *Mind*. He was associated with Prof Bain in the editing of Grote's "Aristotle," and was the author of the volume on Hobbes in Blackwood's series of "Philosophical Classics." He also contributed to the latest edition of the "Encyclopædia Britannica."

DR GEORGE DIXON LONGSTAFF died at Wandsworth on Friday last in his ninety-fourth year. When a young man he was assistant to Dr Hope, Professor of Chemistry at the University of Edinburgh, and he is believed to have been the first teacher of practical chemistry to medical students in this country. He was one of the founders and a vice-president of the Chemical Society of London.

Students of folklore will be sorry to hear of the death of Reinhold Kohler, librarian at Weimar, where he was born in 1830. He died on August 15. Dr. Kohler was a man of great learning, well known as an authority on the subject in which he was chiefly interested.

THE American Academy of Arts and Sciences has published an excellent "Memorial" of Joseph Lovering, who was a Fellow of the Academy from 1839 to 1892, Corresponding Secretary from 1869 to 1873, Vice-President from 1873 to 1880, and President from 1880 to 1892. Mr. Lovering was born on December 25, 1813, and died on January 18, 1892. The "Memorial" consists chiefly of speeches delivered, and letters read, at a meeting held for the commemoration of his life and services, with a biographical sketch by Prof. J. P. Cooke, Secretary of the Council, and a list of Prof. Lovering's publications. At this meeting the chair was taken by Dr. A. P. Perbody, who said that there was a certain fitness in his leading the proceedings, as Mr. Lovering had been his pupil. Speaking of Prof. Lovering as a teacher of physical science, Prof. J. P. Cooke said: "He was one of the best lecturers I have ever known, and I have known the greatest masters of my time."

DURING the past week the weather has been of a decidedly cyclonic type, large disturbances have reached us with considerable frequency from the Atlantic, and have mostly passed to the northward of Scotland. The winds have been moderate to strong from the south west, but have at times attained the force of a gale at places in the north and west, while on Tuesday they were boisterous in all parts of the United Kingdom. The rainfall has been somewhat heavy in the north and west, but light in the southern parts of the kingdom, where, during the first part of the period, the weather was generally fine, with occasional mist or fog in the mornings. The temperature has, on the whole, been mild, the day readings ranging from 60° to 65° over most parts, while in the extreme south they have exceeded 70° on several occasions. The *Weekly Weather Report* published on the 24th instant shows that some of the night minimum temperatures during that week were very low for the time of year, the shade thermometer falling to 25° in the east of Scotland, and to between 28° and 31° in most other parts.

AMONG the valuable discussions which appear in the *Reperitorium für Meteorologie*, issued under the authority of the St. Petersburg Academy of Sciences, is one in vol. xiv., by B. von Nasackin, on the Storms of the Baltic, being in fact a continuation of similar works (by other authors) for the Black and White Seas. The data used in the discussion are taken chiefly from lightkeepers' journals and stations on the coast. The general results show that the yearly frequency of storms differs considerably in different years, and the number of storms at individual stations also varies considerably. In the western part of the Gulf of Finland and in the south of the Baltic storms are much more frequent than in the other parts. The mean wind direction lies between south and west, and the principal storms occur from the same direction, and also between west and north. The maximum number occurs almost everywhere in December, and the minimum in August.

*Das Wetter* for August contains an article by Dr. R. Assmann on the treatment of persons apparently killed by lightning. The different effects on persons struck would prove that the intensity of the flash is subject to considerable fluctuations, and recent photographs of lightning, in fact, show that in addition to the principal flash there are always weaker ones branching out in all directions, like the roots of a tree. It may therefore well be assumed that the intensity of the latter is considerably less than that of the principal current. He quotes a case near Berlin in the summer of 1891 where a number of soldiers were struck by lightning, among them an officer, and a bugler holding his horse, were both struck. The officer shortly afterwards recovered, while the bugler was to all appearances dead, but the officer at once adopted the method of artificial

respiration as applied to the apparently drowned, by which means the bugler was gradually brought back to life. Dr. Assmann states that there can be little doubt that if this method were applied soon after the stroke, and continued for at least a quarter of an hour, many of those apparently killed might be restored to life.

A VALUABLE paper by Prof. L. W. Hilgard, on the relations of soil to climate, has been published by the U. S. Department of Agriculture. Soils being the residual product of the action of meteorological agencies upon rocks, it is obvious, as Prof. Hilgard says, that there must exist a more or less intimate relation between the soils of a region and the climatic conditions that prevail, or have prevailed, therein. Prof. Hilgard discusses, both from a theoretical and from a practical point of view, some of the more important phenomena dependent on this correlation, and their effects on the agricultural peculiarities of the chief climatic subdivisions.

HERR K. FLEGEL gives, in the *Illustrierte Zeitung* for September 12, an interesting account of an archaeological discovery he has made this summer in the island of Kalymnos, near the coast of Asia Minor. At a height of about 220 metres, not far from Emporio, he found the remains of an ancient fortress which seems to belong to the same class of buildings as those of Mycenæ and Tiryns. The remains, which are comparatively well preserved, include Cyclopean walls and a tower. A gateway (11 metres in breadth), the forecourt, a cistern, and a stone oil press survive. In the valley of Vathy, Herr Flegel came upon the remains of walls of an acropolis, which he describes as older than the fortress of Emporio.

IN the new instalment of the proceedings of the Liverpool Geological Society (Part 4, Vol. VI.), Mr. J. J. Fitzpatrick has some interesting notes on the Deep Dale Bone Cave near Luxton. In a paper read before the society in 1890, Mr. Fitzpatrick called attention to this cave, and described the various objects of interest which had been found in it up to that time. In his present paper he gives an account of the results of more recent researches carried on by Mr. W. Millet, of Buxton, by whom the cave was discovered. At the entrance is a refuse heap, three feet thick at the top, extending ten feet on either side of the entrance, and sixty feet down to the stream at the bottom of the dale. Among the objects found in this refuse heap are bones of the horse, stag, Celtic shorthorn (*Bos longifrons*), dog, pig, sheep, goat, wild boar, three flint flakes, a piece of bronze with Celtic pattern, fragments of pottery, including Samian ware, pseudo-Samian ware, Romano-British ware, coins of the Emperor Claudius, and female ornaments, including fibulæ, earrings, brooches, and rings. At the bottom of the heap were found two flint arrow heads. In the second chamber of the cave a hole, eight feet deep, has been dug. The upper bed, three feet thick, is composed of dark clay, with angular fragments of limestone. The second bed, which is from six to sixteen inches thick, consists of broken fragments of stalagmite, limestone, and gravel. In this a human jawbone has been found. The third bed, the thickness of which has not been ascertained, consists of a stiff yellow clay, containing large pebbles, two of which have been artificially pointed at one end. The human jawbone has twelve teeth, with the enamel and dentine in an admirable state of preservation. There were originally fourteen teeth, the two "wisdom teeth" not having been developed at the time of the death of the person to whom the jawbone belonged. The mark of the weapon which gave what was perhaps the death wound is distinctly visible. The weapon penetrated deeply into the bone in a slanting direction, with an upward inclination, and the blow must have been struck from behind. Another object found in the second chamber is a small bronze box, filled with

grew a-her, supposed to be the ashes of a cremated person. The lid is moulded with the raised zigzag pattern common in Roman ornamentation, the hollow parts being lit in with red and green enamel. In the lower chambers, as stated in Mr Fitzpatrick's former paper, the following mammalian remains have been found — A skull of the brown bear (*Ursus arctos*), a skull of the Celtic shorthorn (*Bos longifrons*), teeth of the reindeer (*Cervus tarandus*), and of the red deer (*Cervus elaphus*), part of the skull of the wild boar (*Sus scrofa*), and some human bones.

THE July number of the *Korean Repository* opens with an article by the Rev. Dr. Edkins on the Persians in the Far East. He shows from native sources that at a very early period the influence of Persian ideas penetrated into China. The wide acceptance of these ideas was due in part to the doctrine of a future life, but Dr. Edkins attributes even more importance to the worship of the god of fire as the special ruler of the hearth and the god to be worshipped by newly married people. This, he says, is so adapted to the natives of Eastern countries with their strong family instincts, that it has easily kept its place and still has a firm hold on the popular mind. In another article a writer who signs himself "Victor" indulges in much enthusiastic admiration of Korea and the Koreans. He is especially emphatic in his praises of the scenery around Seoul, with its "grand amphitheatre of granite hills." "The city wall," he says, "climbing over the most precipitous ridges, the sentinel peaks of Nam San, with its cincture of fine trees, and the bold castellated rocks of Poukan, which on the south and north respectively keep guard over the capital, with many other points both within and without the walls commanding varied and extensive views, would alone in any tourist frequented land make Seoul a show place of the guide-books." The ordinary Korean he describes as "a docile and happy creature."

WE learn from *La Nature* that M. Olivet, of Geneva, have brought out a new system of electric heating applied to conservatories, which may prove very useful where a motor force is at one's disposal. A dynamo, worked by some motor, sends the current into receivers of special metallic composition, which become rapidly heated, but without exceeding a certain temperature. A heated air current is set up as with steam-heating. The advantages of the system are: Absence of all unwholesome gas or vapour which might injure the plants, simplicity of construction in the parts conveying the energy, perfect safety as regards heat, which can be regulated at will, convenience and rapidity in starting and extinction, and cleanliness.

MR. A. C. MACDONALD, of the Agricultural Department of Cape Colony, refers with much regret (in the official publication of the Department) to the senseless way in which the ant-bear is being exterminated. This animal, he says, is one of the few indigenous four-footed friends of the Cape farmer. "Its food is the ant, more especially the white ant, an insect which feeds on our crops and the succulent herbage of the veld, and which does much greater damage than is generally supposed. Although the ant has numerous enemies (among which is reckoned the koran, a bird which I am happy to say is now being preserved on some farms solely for this purpose), yet none are so destructive to its welfare as the ant-bear. It is only when on the surface of the ground that the ant runs any danger from its winged foes, but above or below ground it is always within reach of the ant-bear. But it is not only as a destroyer of ants that the ant-bear is of value to the farmer. A large percentage of the seeds of our herbage, after they have dropped off the plant on the hard ground, lose their germinating power from being exposed day after day to the scorching rays of the sun. The ant-bear, as it goes scratching about for ants, covers a large number of seeds with loose earth, in which congenial bed they will retain their repro-

ductive power for a long period, awaiting the moisture from the skies to shoot out and propagate their kind. And yet this animal, harmless in other respects, is being slowly but surely exterminated. For its skin, which is valued at about 15s., and also for its flesh, which resembles superior pork, it is sought after by the natives. With the white race 'sport' is the inducement, this fun taking the form at times of forcing the poor brutes out of their holes by flooding with water, or drowning them and digging them out afterwards."

PROF. G. C. CALDWELL, of Cornell University, has been making oleomargarin a subject of careful investigation, and presents the results of his researches in a valuable paper in the September number of the *Journal of the Franklin Institute*. He thinks that if made of unsuitable materials, oleomargarin may contain germs of disease, and that the process of manufacture ought to be carefully inspected by capable officials, but there is no positive proof, he says, that it is now, or ever has been, made of such materials, or that any disease has ever been communicated to man by its use. He is also of opinion that, when properly made from fresh and clean materials, it differs but slightly in healthfulness from butter. He records, however, a rather significant incident which has recently come to his knowledge. At an asylum for blind children, in Louisville, Ky., where good butter had been supplied, good oleomargarin butter was substituted. No notice was given of the change, and even if the appearance of the substitute would have betrayed it, the blind children could not have seen it. There was no evidence that they were in any way conscious of the change, but it was observed that they gradually ate less and less of the new butter and finally they declined it altogether. No bad effect on their health could be discerned. They made no complaint in answer to the inquiry as to the reason for not eating the butter other than that they did not care for it. It was as if it did not adapt itself to any need of the system. "This," says Prof. Caldwell, "certainly must be allowed to count against the complete fitness of oleomargarin as a substitute for butter."

A FIELD NATURALISTS' CLUB was formed last year in Trinidad, and seems likely to do much useful work. It publishes a journal, and in the third number, which we have received, gives reports of its meetings from the beginning. In the meeting on January 8 Mr. Mole announced that he had found a *Peripatus Edwardsii* in the St. Ann's Valley, and Mr. Urlich stated that he also had found a specimen of the same species at Azouca.

THE report of the Government Central Museum, Madras, for 1891-92, has been published. In an interesting appendix Mr. H. Warth, the officiating superintendent, gives an account, among other subjects, of the tin district in Burma. The tin-bearing deposits are, he says, of two kinds. First, there is the tin gravel which is found in all or most of the valleys, a mixture of rough white quartz pebbles with sand, garnet, black tourmaline, and grey cassiterite. The thickness of the gravel varies from 1 to 6 feet, and the yield of cassiterite may be put down as at least  $\frac{1}{4}$  per cent. or 1 pound of cassiterite (tin dioxide) in 400 pounds of gravel. There are washings going on at many places, but some valleys have been more or less exhausted. The work suffers also under the disadvantage that the greater part of the country is quite uninhabited, that food has to be brought from a distance, and that there is always danger of sickness. Chinamen are the chief workers. The second kind of tin-bearing deposit is the original eruptive rock, which is weathered so that it is possible to wash out the grains of whitish cassiterite which it contains. Mr. Warth visited the principal deposits of this kind near Malewun in July 1891. He took samples from several excavations and washed them. The mean is a yield of only 0.04 per cent. of impure wash tin.

Thus one pound of impure tin dioxide requires 2500 pounds of weathered rock. The rock is traversed by a series of parallel veins of white quartz indicating the origin of all the white quartz pebbles in the tin-bearing gravels, these gravels being nothing but the accumulation, during probably thousands of years, of the washings from the elevated outcrops of tin-bearing eruptive rock. The original tin-bearing deposit of weathered rock has been washed during a good many years. It requires a very good supply of water and very large deposits, otherwise the labour would be far too great and such works could not compete with those in the gravels. Among the rock specimens of the district are also grey limestones from Mount Tampra, three days' canoe journey from Lenya. This mountain Mr. Warth found fringed with caves which most likely owe their origin to the action of the sea. As they are now 160 feet above the sea, it appears that the land has been raised that much in comparatively recent time. If so, then the time during which most of the tin gravels formed was also comparatively limited.

THE third part of the tenth annual report of the Board of Fishery for Scotland has just been issued. It deals with the scientific investigations carried on during 1891. First there is a general statement of the results achieved, then comes a series of general reports, and these are followed by papers recording biological investigations. Finally, Dr. I. Wemyss Fulton gives an account of contemporary scientific fishery investigations in this and other countries. The following are the papers dealing with biological investigations. On the food of fishes, by W. R. Smith, observations on the reproduction, maturity, and sexual relations of the food fishes, by Dr. I. W. Fulton, additions to the fauna of the Firth of Forth, part iv, by Thomas Scott, contributions to the life histories and development of the food and other fishes, by Prof. McIntosh, F.R.S., on two large tumours in a haddock and a cod, by Prof. Prince and Dr. J. L. Steven. We may note that the volume is enriched with many admirable plates.

MESSRS. R. FRIEDLANDER AND SON, Berlin, have just issued the sixth annual report (for 1890) of the ornithological stations of observation in the kingdom of Saxony. The report has been prepared by A. B. Meyer and F. Helm, who have evidently spared no pains to make their work thorough and accurate. In an appendix observations relating to other animals in Saxony, besides birds, are recorded. There is also a list of the birds which up to the present time have been observed in that country, with notes as to their geographical distribution elsewhere.

THE Clarendon Press has reprinted Mr. J. G. Baker's "Summary of New Ferns discovered or described since 1874."

A WORK on "The Great Barrier Reef of Australia, its Products and Potentialities," by Mr. W. Saville-Kent, is to be issued by Messrs. W. H. Allen and Co. The barrier reef of Australia, represented by a vast rampart of coral origin, extends for no less than twelve hundred miles from Torres Straits to Lady Elliot Island on the Queensland coast. Between its outer border and the adjacent mainland it encloses a tranquil ocean highway for vessels of the heaviest draught. To the naturalist, and especially to the marine biologist, the entire barrier is described as "a perfect Eldorado, its prolific waters teeming with animal organisms of myriad forms and hues, representative of every marine zoological group." The author's object will be to render an account, in clear and popular language, both from a commercial and from a biological standpoint, of the most attractive subjects connected with the barrier region. There will be sixteen plates in chromolithograph, with grouped illustrations produced from original water-colour drawings by the author, and forty-eight plates in photomezzotype from original negatives.

NO. 1196, VOL. 46]

THE New Zealand Institute has published its Transactions and Proceedings during 1891 (vol. xxiv, seventh of new series). The volume is edited by Sir James Hector, and contains many papers of considerable interest and value. The papers presented in the Transactions are grouped under the headings of Zoology, Geology, Botany, and Miscellaneous. The Proceedings include those of the Wellington Philosophical Society, the Auckland Institute, the Philosophical Institute of Canterbury, the Otago Institute, the Westland Institute, the Hawkes Bay Philosophical Institute, and the Nelson Philosophical Society.

THE *Journal of Botany* for September gives an account of the results of M. J. Bornmuller's botanical exploring expedition in Persia. The flora of the district visited is a very abundant one, but not many new forms were gathered. The mountain sides of Kuh Jupar, at a height of between 2900 and 3000 metres, were covered with dense forests of an undescribed species of *Ephedra*.

THE number of the *Oesterreichische Botanische Zeitschrift* for September is almost entirely devoted to the discussion of the question of botanical nomenclature, and the opinions on the various disputed points, of the leading English and Continental botanists.

MESSRS. CROSBY, LOCKWOOD AND SON announce the following works:—"The Microscope: its Construction and Management," by Dr. Henri von Heurck, Director of the Antwerp Botanical Gardens, translated from the French by Mr. Wynne E. Baxter, F.R.M.S.; "Electric Ship Lighting: a Practical Handbook for Electrical Engineers and others," by J. W. Urquhart; "Toothed Gearing: a Practical Handbook for Office and Workshop," by a Foreman Pattern Maker, author of "Pattern Making," &c.; "The Mechanics of Architecture: a Text-book for Students," by E. W. Tarn; "The Visible Universe: Chapters on the Origin and Construction of the Heavens," by J. E. Gore; "The Health Officers' Pocket Book for Medical Officers of Health, Sanitary Inspectors, Members of Sanitary Authorities, &c.," by Edward F. Wilmoughby, M.D. (Lond.); "The Art and Science of Sail Making," by Samuel B. Sadler, practical sail maker; "The Complete Grazier and Farmers' and Cattle Breeders' Assistant: a Compendium of Husbandry, originally written by William Zinatti, thirteenth edition, entirely re-written, considerably enlarged, and brought up to the present requirements of Agricultural Practice," by William Freem, LL.D.; "Farm Live Stock of Great Britain," by Robert Wallace, professor of Agriculture and Rural Economy in the University of Edinburgh, third edition, thoroughly revised and considerably enlarged; "Tramways: their Construction and Working," by D. Kinnear Clark, M.Inst.C.E., new edition, thoroughly revised, in one volume; "The Wood-worker's Handy Book: a Practical Manual embracing information on the Tools, Materials, and Processes employed in Wood-working," by Paul N. Hasluck; "The Metal-worker's Handy Book: a Practical Manual embracing information on the Tools, Materials, and Processes employed in Metal working," by Paul N. Hasluck; "Practical Lessons in Roof Carpentry," by Geo. Collings; "The Steam Engine: a Practical Manual for Draughtsmen, Designers, and Constructors, translated from the German of Herman Haeder, revised and adapted to English Practice," by H. H. P. Powles.

MESSRS. BELL AND SONS are about to publish the following books:—"The Student's Hand-book of Physical Geology," by A. J. Jukes-Brown, with numerous diagrams and illustrations, second edition, revised and much enlarged (Bohn's Scientific Library); "Sowerby's English Botany," Supplement by N. E. Brown, of the Royal Herbarium, Kew (to be completed in eight

or nine parts), "Fungus Flora," a classified text-book of Mycology, by George Masee, author of "The Plant World," with numerous illustrations, 3 vols., vols. 1 and 2, "The Framework of Chemistry," Part 1, by W. M. Williams.

UNIVERSITY COLLEGE, Liverpool, has issued its prospectus of day classes in arts and science, and of the evening lectures, for the session 1892-93.

PART 48 of Cassell's *New Popular Educator*, with title-page and contents to vol. VIII, has been issued. The next monthly part of the work will form the first part of a technical series of Cassell's *New Popular Educator*, published under the title of Cassell's *New Technical Educator*.

MESSRS. DUNLOP AND CO. have published a catalogue of works on electricity, galvanism, and magnetism—works which they offer for sale.

FOUR lectures on Cholera will be delivered by Dr. L. Symes Thompson in Gresham College on October 4, 5, 6, and 7, at six o'clock p.m. The lectures will be free to the public.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♂) from India, presented by Mrs. Trafford Rawson, a Green Monkey (*Cercopithecus callithrix* ♂) from West Africa, presented by Mr. A. de Turckheim, two Tigers (*Felis tigris* ♂ & ♀) from India, presented by the Maharaja of Oodeypore, a Grey Ichneumon (*Ichneumon griseus*) from India, presented by Mr. Hugo Marshall, a Three striped Paradoxure (*Paradoxurus trivirgatus*) from Java, presented by Mr. Douce, a Jackdaw (*Corvus monedula*), British, presented by Lt. Col. R. F. Darvall, F.Z.S., a Common Fox (*Canis vulpes*), British, presented by Mr. Lucius Fitzgerald, an Indian Cobra (*Naja tripudians*), an Indian Rat Snake (*Ptyas mucosa*) from India, presented by Mr. Arthur H. Cullingford, F.Z.S., a Common Boa (*Boa constrictor*) from St. Lucia, W.I., presented by H. L. St. Walter F. Hely Hutchinson, K.C.M.G., a Common Chameleon (*Chamaeleo vulgaris*) from North Africa, presented by Miss Withers, two Tarantula Spiders (*Megale*, sp. inc.) from Demerara, presented by Mr. H. Strong, a Black-headed Lemur (*Lemur brunneus* ♀) from Madagascar, a Dwyker Bok (*Cephalophus marginatus* ♂) from South Africa, two Demoiselle Cranes (*Grus virgo*) from North Africa, four Emus (*Dromaeus novaehollandiae*) from Australia, deposited, an Indian Chevrotain (*Tragulus meminna*) from India, two Violet Tanagers (*Euphonia violacea*) from Brazil, a Shag (*Phalacrocorax gracilis*) British, purchased, three Wild Swine (*Sus scrofa*) born in the Gardens.

### OUR ASTRONOMICAL COLUMN

THE VARIATION OF LATITUDE AT PULKOVA.—*Astronomische Nachrichten*, No. 3112, contains two communications on the variation of the latitude at Pulkova, the first by Mr. B. Wanach, who discusses some old observations, and the second by Mr. S. Kostinsky, who has continued the former's recent observations made before July, 1891. During the years 1890 and 1891, Mr. Wanach obtained some very definite results with regard to this question by using the large Pulkova transit instrument in the Prime Vertical, and the object of the present discussion is to find out if any like result can be discovered. The observations used are those of W. Struve made between the years 1840-55, O. Struve 1858-9, Oom 1861-63, and Nyren 1879-82. If we employ those made in the years 1840-42 it is at once noticed that to satisfy the conditions a variation in the height of the pole of  $\pm 0''.1$  has to be assumed, while the maxima and minima occur at different months of the year, the latter on September, 1840, May, 1841, March, 1842, and the former on January, 1841, September, 1841, and October, 1842. The observations from 1843-63 present no direct fluctuations in the value of the mean pole height, but show that it remains constant

or is proportional to the time during the whole period. Taking the values of the mean pole height for the years 1879-82, as obtained from a similar curve, it is found that a single sinus curve is not sufficient for the comparison, secondly, that the mean pole height is not the same as it was in 1841 and 1891, but is about  $0''.15$  greater, thirdly, that the chief maximum on March, 1881 coincides with the chief minimum on September, 1880, that is, exactly coincides with the phases of the pole height. It also happens that the series, which take more than two years, give only one distinct maximum and minimum (instead of two, as would be expected). Coming now to Mr. S. Kostinsky's work, whose observations were made by W. Struve's method with the aid of a large transit instrument by Repsold, the variation of latitude is clearly shown. With the aid of the curve, which accompanies the paper, the maximum of the latitude occurs on October 4, 1891. Owing to the observations not being quite complete, the epoch of minimum is uncertain, but the curve shows that it will take place somewhere before the end of the month of May 1892. Comparing this curve with that obtained by Mr. Wanach in the year 1891, we have for the dates of the greatest and least values of the latitude—

Max in 1890, September 14	$\phi = 59^{\circ} 46' 18'' 39$
Min " 1891, April 15	17 79
Max " 1891, October 4	18 44
Min " 1892, May 20-31 (about)	

DOUBLE STAR OBSERVATIONS.—The second part of Appendix I to the *Washington Observations for 1888* contains the observations of double stars made at the United States Naval Observatory during the period 1880-1891, by Prof. Asaph Hall. These observations have been made with the intention of carrying on the work that was begun with the same instrument in 1875. The stars here observed are mostly known binaries. Some are of special interest on account of their short periods, while again the motion of others will be found to be very slow. This volume will be welcomed by all double star observers, for in such a work as this a strict comparison of observations is needful in such measurements as are here dealt with. The form in which the observations are printed is the same as was the case in 1881. The star's name is first given, followed by its right ascension and declination, and its magnitude. In the first column the date of observation in years and decimals of a year is given, while in parallel columns the sidereal time of observation to the first decimal of an hour, position angle, distance, and weight of observation are similarly inserted, in two other columns the magnifying power employed and occasional notes are added for reference. The volume concludes with an index of all the stars observed. The numbers of the stars are for the most part those of the Struves, but Prof. Hall, in recording those faint stars in the Pleiades, has referred them to Bessel's list of fifty-three stars in this group. Bessel's stars themselves he has numbered in the order they appeared in the *Astronomische Untersuchungen*, first volume, p. 237.

SOLAR OBSERVATIONS AT ROME.—In the August number of the *Memorie della Societa degli Spettroscopisti Italiani*, Prof. Tacchini contributes, in tabulated form, the results of the solar observations made at the Royal Observatory during the second three months of this year. Considering first the faculae, they seemed most numerous on the southern hemisphere, there being an excess of 13. Latitudes  $20^{\circ}$  to  $10^{\circ}$  north, and  $20^{\circ}$  to  $30^{\circ}$  south, were the zones of greatest frequency, the number recorded being 49 and 50 respectively. Taking the whole numbers for both hemispheres the table shows a distinct increase, the numbers for the three months being 71, 75, and 97. With reference to the spots, the two hemispheres seem to have been evenly distributed, the numbers seen amounting to 48 and 46 respectively. The zones of greatest frequency were found to be  $\pm 10^{\circ} \pm 20^{\circ}$ , the number of spots recorded being 29 and 22; but in zone  $-20^{\circ}$  to  $-30^{\circ}$  as many as 19 were noted, the number in the corresponding zone of the northern hemisphere amounting only to eight. The record of eruptions for this period is not very high, six only being seen in the northern and three in the southern hemisphere, the zone of maximum frequency for the northern hemisphere is  $+10^{\circ}$  to  $+20^{\circ}$ , the same as that for spots, the six observations occurring in this zone alone, for the southern hemisphere the three eruptions were observed in each of the  $10^{\circ}$  zones included between  $-10^{\circ}$  and  $-40^{\circ}$ .

## GEOGRAPHICAL NOTES

As the result of recent explorations by Lieutenant Fromm in the southern part of German East Africa, it appears probable that the difficulties which beset navigation on the Rufiji and Rovuma rivers are not so serious as has hitherto been supposed. The resources of the country traversed by these rivers are reported to consist mainly of india-rubber in the forests. An examination of a coalfield reported by Arabs as existing on a tributary of the Rovuma showed that the valuable coal seams were practically confined to the Portuguese side of the frontier.

In a recent number of *Petermann's Mittheilungen*, Dr. Karl Grissinger publishes an interesting investigation of the physical conditions of the Weissensee in Carinthia. The paper is accompanied by a bathymetric chart, which shows that the lake belongs to the same class as the long, narrow, deep lakes of Scotland, and by a remarkable diagram of temperature changes. The latter is constructed so as to show the diurnal change of temperature at all depths from hour to hour for four consecutive days, and is in a high degree interesting and instructive. Diurnal change of temperature becomes imperceptible at a depth of 37 metres, and the hour of maximum temperature is retarded as the depth increases. Thus the surface maximum occurs about noon, while that at a depth of 25 metres is not attained until 8 a.m. of the following day.

A RECENT official estimate of the coast line of the United States, including islands, indentations, and estuaries, gave as the total 90,900 miles. Of this the Atlantic Ocean accounted for 36,500 miles, the Gulf of Mexico for 19,100, the Pacific Ocean for 8,000, and Alaska for 26,400. Considering only the general coast lines, neglecting estuaries, bays and islands, the Atlantic margin measured 2000 miles, the Gulf of Mexico and Pacific Ocean 1800 each, and Alaska 4800, a total of 10,400 miles.

M. J. GAUTIER has elaborated a system of photographic surveying, which is attracting considerable attention in France in view of the approaching revision of the cadastral survey of that country. By means of a specially mounted camera, a series of twelve views are taken from one point, so as to comprise the entire horizon. A set of signals, the position of which is carefully arranged, enable the various plates to be afterwards fitted together. The map is subsequently traced out on waxed linen by a sharp point, a faintly printed copy of the photograph serving as a basis.

THE uncertainty of communication with the Upper Nile valley makes it difficult to determine the precise weight to give to reports of events happening there. But it appears highly probable that an expedition from the Congo Free State has at last succeeded in establishing a station at Wadelai, or some other point within the British sphere of influence. The natural outlet of the region is of course down the Nile, and it is scarcely in accordance with the principles of geography that a prosperous development can ensue with so difficult an outlet as that to the Congo. The practical aspects of the case are in their present stage more political than physical, and in this stage they are likely to remain for some time.

ON Tuesday the *Times* printed the following telegram, dated September 26, from its Calcutta correspondent:—Mr. Conway's mountaineering party, which left Askoley on July 31, reached the foot of the Baltoro Glacier after four days' march, and proceeded up the glacier for four days. They then climbed a peak north of it 20,000 feet high, which they named Crystal Peak, and hoped to get a view of the great peak "K<sub>2</sub>," but it was hidden by a neighbouring peak. They then went another day's march up the glacier and climbed a pass to the east of Crystal Peak 18,000 feet high. From this they saw "K<sub>2</sub>," but discovered that the map was altogether wrong in the representation of the neighbourhood of that peak. They also found the Baltoro Glacier considerably longer than the map makes it. A high peak not marked on the map stands at the very head of the glacier. This Mr. Conway named the Golden Throne. They determined to try the ascent, and went on march further up the glacier and then were stopped by a snowstorm, during which they sent the coolies down to collect firewood. They reached the foot of the Golden Throne on August 18, and then worked up behind the peak, climbing over 2000 feet through a very broken icefall. It took four days to establish and victual a camp above the ice-fall, at a height of 18,000

feet. They moved next day to a camp 19,000 feet, and the day following to one about 20,000 feet high. Thence, on the 25th, they started for a real climb, and having reached a point over 23,000 feet high, they found they were on a mountain entirely cut off from the Golden Throne, which was still 2000 feet above them. The peak they ascended—which they named the Pioneer Peak—commanded a magnificent view, especially in the Hunza direction, where they could see to the distance of at least 200 miles. They suffered from the great altitude, but not severely, and they could have climbed at least a thousand feet higher, and perhaps more. They slept that night in their camp 20,000 feet above sea level. They were obliged to descend next day as their provisions were exhausted. Bad weather commenced on the 27th, and continued, putting an end to climbing for the present season. Mr. Conway has gone to Leh, for the purpose of comparing his barometer with the standard there, and accurately reckoning the height of the Pioneer Peak. He expects that the comparison will show that they attained a height at least a thousand feet above Schlagintweit's 22,230 feet in Nepal, which is the highest climb hitherto authentically recorded. He will then return to India.

## THE IRON AND STEEL INSTITUTE

THE autumn meeting of the Iron and Steel Institute was held last week in Liverpool, under the presidency of Sir Frederick Abel. The meeting was fairly successful on the whole, although the weather marred some of the excursions, and the last day's sitting was simply wasted time. The following is a list of the papers read:—"On the Manufacture of Iron in its Relations with Agriculture," by Sir Lowthian Bell; "On an Apparatus for Autographically Recording the Temperature of Furnaces," by Prof. W. C. Roberts Austen; "On the Alloys of Iron and Chromium," by R. A. Hadfield (Sheffield); "On the Liverpool Overhead Railway," by J. H. Greathead; "On the Engineering Laboratories in Liverpool," by Prof. H. S. Helle Shaw; "On the Furnaces in the Necks of Chilled Rolls," by Charles A. Winder (Sheffield); "On a New Process for the Elimination of Sulphur," by F. Saniter (Wigan); "On the Elimination of Sulphur from Iron," by J. F. Studd (Middlesbrough). A paper on the basic Siemens process, by Mr. Kupelwieser, of Witkowitz, was also on the list, but was adjourned until the Spring Meeting of next year.

Upon the members assembling in St. George's Hall, on Tuesday, September 20, they were welcomed by the Mayor of Liverpool, and the reception formalities being disposed of, Sir Frederick Abel gave a short address, in the course of which he commented on the papers about to be read, and also stated that Mr. L. Windsor Richards, of Low Moor, had been elected by the Council to be President of the Institute, in succession to himself, during the coming two years during which the presidential term lasts.

The first paper on the list was Sir Lowthian Bell's contribution, which he read from MS., the paper not having been prepared in time to be printed. Those who are accustomed to attending meetings of this kind know how difficult it is to follow the reading of a paper even when they have the help of a printed copy, but when one has to depend upon one's hearing only, in a large room and amidst many disturbances, the task is hopeless. So far as we could gather, the author treated his subject *ab ovo*, and much of the first part of the paper might be found in various elementary text books. The main point of interest was a description of an apparatus which has been devised for arresting and securing certain products which are to be extracted from the fumes of blast-furnaces using raw coal. The chief of these by-products is sulphate of ammonia, and the author pointed out how necessary it was to the harmonic working of an economic system that this sulphate of ammonia should be collected and returned to the earth as a fertilizer. Of course, there is no gain-saying this part of the argument, and, as it is perfectly possible to collect the fumes and products of combustion, the question resolves itself into one of profit and loss. Sir Lowthian quoted figures which would, in these lean times, make the ironmaker's mouth water, and almost convert the iron itself into a by-product, but unfortunately, as it appeared afterwards during the discussion, the selling prices which the author had taken were by no means those of the present day. Mr. Snelus spoke of the remarkable fertilizing properties of sulphate of ammonia and

nitrate of soda. He had spread one half of a newly sown lawn with a mixture consisting of one part of sulphate of ammonia to three parts of nitrate of soda—four cwt. to the acre—and had grass an inch long, whilst the unsprayed part was quite bare.

The next paper taken was that of Prof. Roberts Austen, in which was described a modification of the Le Chatelier pyrometer, which has been introduced for the purpose of securing autographic records of temperature. The apparatus was exhibited at the council table, and has been constructed under the directions of the author for Mr. I. P. Martin, of Dowlaish, in order that a continuous record might be kept of the temperature of the stoves in which the blast is heated for the iron smelting furnaces. It will, of course, be understood that the apparatus is suitable for recording temperatures under other conditions, and it can hardly fail to afford valuable assistance to those engaged in many branches of manufacturing industry, and in the scientific investigating of processes, in fact, in many branches of metallurgical inquiry, and also in the study of steam engine economy, there has been no want more widely felt in times past than that of a trustworthy means of ascertaining high temperatures. The author had previously described an apparatus he had before devised, and that shown was the result of a desire to simplify the design. The original apparatus consisted of a camera containing a reflecting galvanometer of the Depretz and D'Arsonval type of about 200 ohms resistance. A thermo junction is connected with this galvanometer, and the amplitude of the deflection of a spot of light from the mirror affords the basis in calculating the temperature to which the thermo junction has been raised. An autographic record of the temperature may then be readily obtained if the spot of light from the mirror falls into a sensitized photographic plate actuated by an astronomical clock, or by other suitable mechanism. Such an appliance as this, though well adapted for conducting investigations, is not sufficiently simple for industrial purposes, and the author determined that it was necessary to simplify the part which receives and records the spot of light, and also to arrange for attaching several thermo junctions, so that there would be one for each furnace, and each might be brought in connection with the recording apparatus in turn. In order to effect these changes the original moving plate was replaced by a clockwork revolved cylinder, to which was attached sensitized paper. In the apparatus shown provision was made for placing any one of six centres of heat, such as hot blast stoves or furnaces, in connection with the galvanometer, and for obtaining within the period of the revolution of the cylinder a record of the temperature of any one, or of all the six sources of heat. The records will, of course, be intermittent, the duration of the test in any particular case being subject to the will of the operator, or the shifting of the electrical contact from furnace to furnace could be carried on by clockwork. The apparatus would then be entirely independent of manual adjustment.

In the discussion which followed the reading of the paper the most important point was that raised by Dr. W. Anderson, the Director General of Ordnance Factories, who asked what was the durability of the thermo couple, and whether the intensity of the current would alter owing to changes in the metals after exposure to high temperature. It will be remembered that the metals used are platinum and rhodium. Mr. I. Parker also asked if the couple was protected. Sir Lowthian Bell, who has had considerable experience with the Le Chatelier pyrometer in practical use at the Clarence Iron Works, said that in regard to durability and constancy of record, the device was most successful. He had only had to renew three or four couples, and they certainly would give accurate readings for the space of several weeks. He had proved this by comparing new and old couples, and also by testing at known temperatures. The author subsequently stated that the couples were put naked in the blast, and did not require protection unless subject to the impact of a shower of metal, in which case they were placed in a porcelain sheath.

Mr. Greathead next read his paper on the Liverpool Overhead Railway. This is a new railway which follows the "Line of Docks," and extends for a distance of about six miles. It is composed, for the whole distance, with the exception of a length of a few hundred feet, of an iron viaduct of uniform height, and which is continuous from end to end, unless some of the swing bridges on its course be open. The railway itself has been previously described, but the rolling stock has not, we believe, before been dealt with. Electricity will supply the motive power, there being a generating station situated about

the middle of the line, where there will be four engines working up to 100 horse power, each driving a separate Elwell Parker dynamo. The current will be carried along the line by a steel conductor placed on porcelain insulators. Hinged collectors of cast iron, sliding upon this conductor, will make the connection between the motors on the train and the generating dynamos. There will be no separate locomotives, the motors being on the cars, two cars forming a train to seat fifty-six passengers, the total weight being about forty tons. The signals will be worked by the trains themselves through an automatic device. The total cost of the railway is to be £85,000 per mile.

The second day, Wednesday, September 21, was opened by the reading of Mr. Hadfield's paper. This is a production of the kind that brings despair to the heart of those who prepare brief notices of these meetings. It consists, with the appendices, of over eighty-three pages, besides numerous sheets of tables, diagrams, &c. It begins with *Vivaquelin*, and ends with a bibliography—*ab ovo usque ad mala*, as the author himself says, but the difficult part of the matter is that throughout the whole treatise there is not a part that could well be left out without disadvantage to the reader. Having said so much it will be evident that we can give but a very faint indication of the contents of Mr. Hadfield's paper. It is well known that he has made a special study of the alloys of iron and chromium, generally known as chrome steel, and his success as a practical steel maker has been most marked. He has now put the results of long research and experiment at the disposal of all steel makers, and we cannot do better than refer those interested in the subject to the original work, which will duly appear in the volume of the proceedings of the Institute. It is noteworthy that chromium appears not to be in itself a hardener of steel, but that it acts indirectly by influencing the action of carbon upon the iron. Some of the photographic reproductions of chromium steel projectiles attached to the paper are very interesting, as showing what punishment this metal will stand. The shells go through nine inches of compound armour and eight feet of oak backing without apparent damage, the points being as sharply defined as in the shell as it comes from the shops. At a range of eighty yards two six-inch shells went through the thickness of armour mentioned, the striking velocity being 1825 feet per second, and the energy 2250 foot tons. One projectile altered 0.1" in diameter and the second 0.13". One of these projectiles was fired through another 9" plate without apparent damage. A 13.5" projectile, also of Hadfield's make, was fired at a target consisting of two armour plates with 20" of oak between. The first plate consisted of 18" of compound armour backed by 6" of wrought iron. Next came the 20" of oak, and then a 10½" wrought iron, and finally a 2" wrought iron plate. This gave a total of 36½" of steel and iron, besides the oak. The penetration was complete, but the illustration shows the projectile to have been broken into three parts. The striking velocity was 1950 feet per second, and the energy on impact 34,280 foot tons. The weapon was a 63-ton B. I. gun.

In the discussion which followed this paper—which the author read in abstract, having previously distributed printed copies—Prof. Roberts Austen pointed out that the author's researches supported the views taken by himself and Osmond as to the dual form in which iron exists. This was shown by the diagrams showing the rate of cooling which accompanied the report. In these, when the cooling was from a high temperature, 1320° C., the curve was continuous throughout, but when the cooling was from about a thousand degrees, there was a point of recovery indicating recalcrescence. The diagrams formed part of a report by Mr. Osmond on Hadfield's chromium steel, which the author had incorporated in his paper. Prof. Roberts Austen said he had arrived at the same results working independently. Another point worth recording is that remarked upon by Mr. Vickers, who dwelt upon the difficulty of deciding whether the effects noted in the steel were due to carbon or chromium, as it seemed impossible to separate the one from the other, the chromium invariably disappearing with the carbon. Mr. Vickers also started the old question of hardening by oil or water, a process which he advocates. Dr. Anderson put the matter in its true light by pointing out the danger from untrustworthiness due to the hardening process, defects being sometimes set up of which there was no outward indication. This, of course, refers to metal in large masses, such as gun hoops, &c. Mr. F. W. Webb, the Mechanical Engineer to the London and North-Western Railway, gave high praise to chromium steel, saying

he used it entirely for springs and also with advantage for tyres. He likewise found it an excellent material for tool steel.

Mr. Winder next read his paper on the failure of chilled rolls. The breakage of rolls is one of the most annoying of the many troubles with which the producer of manufactured iron has to contend. This is a matter which has hitherto received too little attention, it being generally considered to be in the nature of rolls to break, and nothing man could do would prevent it. It is as evident as like produces like, that if some rolls will last for considerable periods of time, others of exactly similar description, and working under the same conditions, would stand equally long. Sometimes four or five rolls—the author instances eleven in a fortnight—will give out one after another, until at last one will be found to accomplish the work. Mr. Winder, as a roll founder, endeavours to bring some sort of order into the process of manufacture. He points out that when a train of rolls is hard at work in the present day they will turn out as much as 1000 tons a week, and the passing of this great weight of red and white hot billets or blooms will be almost equal to putting the rolls into a furnace. The necks of the rolls are, however, kept cool by water, so that the lubricant may not be burnt off, and the sudden cooling thus caused produces a molecular change in the metal which, the author considers, accounts for much of the mischief. In order to overcome this difficulty it is recommended that there should not be too sudden a reduction of the diameter of the body of the roll where the neck is formed. That, in brief, appears to be the author's opinion, and doubtless his advice is good; in fact, it follows one of the cardinal laws observed by good iron founders in the casting of other articles besides rolls. A good practical discussion followed the reading of the paper. We think that foundry practice is a little behind in this country, and in this respect we might, with advantage, take a hint or two from American methods, perhaps more especially in regard to smaller castings than chilled rolls, which often fail unaccountably in the United States also. The advice to roll founders to cast with a bigger head should not be, but apparently is, necessary. Prof. Turner's remarks were to the point, and it would be of advantage if he would make his researches in this direction more fully public.

Prof. H. S. Heli Shaw was the author of the last paper read on the Wednesday of the meeting. The Walker Laboratories form part of University College, Liverpool, and are among the most recent and best arranged establishments of the kind. They have been erected under the guidance of the author of the paper, who occupied the chair of Engineering Science when the school was in a far less magnificent form. We have not space to follow the author in his description of the buildings, or the method of instruction. The latter appears to be framed in a manner calculated to turn out good engineers, a class which cannot be too large for the welfare of the country, although complaints are growing daily that they are already too numerous for their own advantage.

The last day of the meeting was Thursday, September 22, when two papers were read. The first was the contribution of Mr. Saniter, and in it he described the process by which he proposes to remove sulphur from iron by calcium chloride and lime. The experiments quoted go to prove that lime alone removes a considerable quantity of sulphur from iron if the contact is sufficiently prolonged, and, further, that a mixture of calcium chloride and lime completely eliminated the sulphur in the space of half an hour. Chloride of calcium is a by-product of the manufacture of ammonia, of soda (by the ammonia process), and of Weldon's bleaching process. The author states that the production amounts to many thousands of tons, of which only ten per cent finds useful employment, the remainder running to waste. The subject is one of considerable importance, and no doubt the process will be freely criticized when it comes up again for discussion at the next spring meeting.

Mr. J. E. Stead's paper on the same subject—the elimination of sulphur from iron—was a much more imposing contribution, covering 40 pages of the proceedings. It dealt broadly with the whole question, and forms a most valuable contribution to the literature of the subject. At the conclusion of the reading of his paper Mr. Stead said that since it had been written he had had further light thrown on the matter by experiment and otherwise. He therefore proceeded to read from a MS. certain fresh matter, which appeared to occupy as much space as the paper itself. No doubt Mr. Stead will weld the original paper and the additions into one harmonious whole, which will then form a standard work of reference on a sub-

ject which has come to the fore so much within the last year or two. We congratulate Mr. Stead upon his courage in dealing with this matter in the way he has, and especially upon the practical disclaimer of infallibility which the appendix to his paper supplied.

There was no discussion of these papers, their consideration being adjourned until the spring meeting of next year. The matter should be well thrashed out, as speakers will have had an opportunity of consulting authorities, marshalling facts, or even making fresh experiments. It is to be hoped that in the future more discussions will be arranged on similar lines.

The proceedings closed with the usual votes of thanks to those in Liverpool to whom the Institute was so largely indebted for the success of the meeting.

There were several excursions during the week. The chief of these were to the Manchester Ship Canal, the Vyrnwy Water Works, the Lancashire and Yorkshire engineering shops at Horwich, the Liverpool Overhead Railway, and Laid's shipyard. A visit was also paid to the Walker engineering laboratories, where Prof. Heli Shaw had collected some very interesting models for the occasion. The most striking of these was an exceedingly intelligent chain making machine, which has recently come over to this country from the United States. The whole of the operations are automatic, reels of wire going in at one end of the apparatus, and coming out one continuous length of chain at the other, and this without human intervention of any kind. The machine, in the ingenuity of its design, rank with Laycock's horseshoe loom, which we described in connection with the visit of the Institution of Mechanical Engineers to Sheffield of two years ago. It is really surprising to see what complicated operations mechanism may be made to perform by means of cams, levers, and springs. Mr. Laycock's loom exhibited perhaps a higher intelligence than the chain making machine, inasmuch that it would select suitable hairs from a bundle, and would refuse to continue the work unless the proper kind were supplied. The chain making machine, on the other hand, has to deal with a more stubborn material and has to connect each link. We do not know the name of the inventor of this machine, but the chain is known as a Triumph Chain.

## FUELS AND THEIR USE

At the annual meeting of the Society of Chemical Industry, held in London on July 20, the chair was occupied by Dr. J. Emerson Reynolds, F.R.S. He chose, as the subject of his presidential address, "The modern developments in regard to fuels and their use"—a subject, as he explained, which had occupied much of his attention. The address was one of popular, as well as of scientific, interest.

After some preliminary remarks, Dr. Reynolds said:—

The fuel question is one which concerns those of us who live on the western side of St. George's Channel even more seriously than it does you, as our coal beds have been washed away in ages past, and of native fuel there is practically none save peat, hence industries which require large quantities of cheap coal cannot flourish in Ireland under existing conditions. It is, therefore, our interest to watch closely the development of improved and economical methods of using such fuel as we can obtain from other countries, and apply them in the utilization of our bulky but abundant peat. It is evident that no other fuels need be considered save coal, peat, and petroleum, hence, my remarks can take somewhat the form of a trilogy, minus the dramatic element, precedence being given to the solid fuels, and the first place necessarily to coal.

The Royal Commission on Coal Supply, which commenced its sittings in July, 1866, and reported in July, 1871, after inquiring into all probable sources of coal in Great Britain, arrived at the conclusion that not more than 146,480 million tons were available at depths not exceeding 4000 feet from the surface. Therefore, at our present rate of increase of population and of coal consumption, our supply would not last for 230 years. But Mr. Hall, one of Her Majesty's Inspectors of Mines, who has special experience of coal mining, forms a much lower estimate of the supply practically available with our present means, and considers 170 years as the more probable duration of our coal beds. This estimate is based on fuller information than that possessed by the Royal Commissioners, we are therefore justified in concluding that the inhabitants of Great Britain 170 years hence will have little, if any, home raised coal to burn if we continue to use it in our present wasteful fashion.

It was pointed out by the Royal Commissioners in 1871 that we cannot suppose 'the production of coal could continue in full operation until the last remnant was used, and then suddenly cease. In reality a period of scarcity and dearth would first be reached. This would diminish consumption and prolong duration, but only by checking the prosperity of the country.' 'Much of the coal included in the returns could never be worked except under conditions of scarcity and high prices. A time must even be anticipated when it will be more economical to import part of our coal than to raise the whole of it from our residual coalbeds.' As the area of coal bearing strata in North America is fully seventy times greater than ours, it is easy to see where our future supplies must come from. The rate of increase in the use of coal has been greater than the Commissioners anticipated in 1871, and Mr. T. Foster Brown, C.F., President of Section B of the British Association at Cardiff last year, has placed on record his opinion that at the end of only fifty years from the present time the increased cost of coal will be severely felt. Pessimism is never pleasant, nevertheless we cannot afford to ignore reasonable inferences from fairly ascertained facts.

I apprehend that there are few ordinary consumers likely to be influenced in avoiding waste by the knowledge that we are within measurable distance of the end of our store of British coal, as that calamity may still be some generations off. But the case is very different with large consumers, the inevitable, if gradual, increase in the cost of coal has effectually arrested the attention of those directly concerned in our great industries or anxious for the maintenance of that manufacturing supremacy to which this country chiefly owes its wealth and power. Keen international competition in trade has quickened the effort to get the utmost work out of fuel, and therefore to diminish waste.

No such considerations have, however, produced any effect on the domestic conscience. A spasmodic increase in cost of coal stimulates the use of various economical devices which are almost wholly given up when prices fall back nearly to their former level. A small residual effect is left, which, though slight, is on the right side. But that economy in the domestic use of coal which could not be effected by a patriotic desire to avoid the too rapid exhaustion of our coal beds, or by a fear of permanently dear coal, is likely to be brought about by the growing nuisance of large towns, namely, fog, for whose increase our 'hearth and homes' are in a greater degree responsible than the much abused factory chimneys. The primary consideration in seeking to cope with the fog demon no doubt is to avoid the production of solid particles during the combustion of any fuel we may use, hence that method which avoids the formation of smoke at any time, and is both more convenient and economical, must ultimately 'hold the field.' As you well know, various suggestions have been made for the purpose of avoiding the production of smoke, and it has even been proposed that the use of non-flaming coal should be made compulsory in all large towns, notwithstanding the difficulties known to attend the combustion of anthracite or similar substances in open grates. But even if the fog demon could be satisfactorily exorcised by such means, the fact would remain that the combustion of any solid fuel in an open grate is a most wasteful proceeding. On the other hand, closed grates or stoves have not been popular in these countries. How, then, can we combine economy in the use of coal with smokeless combustion and domestic convenience? The answer is sufficiently obvious—we must more or less completely gasify the coal prior to its complete combustion.

The late Sir William Siemens showed us long ago how to convert coal completely into gas by means of his great 'producer' furnaces, and demonstrated the applicability of the comparatively poor 'producer' gas to operations requiring very high temperatures as well as to the minor work of steam raising. Siemens showed that when so used one ton of coal can perform as much work as 1.7 tons directly burned. In such comparisons the 'producer' gas was, of course, burned at a short distance from its source and under the regenerative system. This mode of using coal seems to be the most economical of which we have practical experience, but the gas which is produced seldom contains less than 65 per cent. of useless nitrogen, and therefore is not rich enough in combustible matter for general distribution.

The Wilson method of gasifying coal and that employed by the Leeds forge, permit the production of a richer gas

The Wilson process involves the formation of a certain proportion of 'producer' gas in raising the temperature of the coal up to the point at which it can decompose steam, and then affords a mixture of carbon monoxide and hydrogen, or so called 'water gas.' The former can be used for steam raising or furnace work in the immediate vicinity of the producer, while the water gas can be transmitted through mains as readily as ordinary town gas, and loses nothing by carriage save its initial heat. Thus one general method affords two qualities of fuel and gasifies the coal in an economical manner.

Whether by the Siemens method in its modern form or by the more or less complete conversion into rich water gas, a great saving in coal can now be secured in almost all large operations requiring the command of high temperatures, and the use of such gaseous fuel is so steadily extending that we may expect in the near future to reach the maximum practicable economy of coal in our greater industries and of smoke abatement as well.

Between the complete conversion of coal into gas and the very partial process included in the production of ordinary illuminating gas is a wide gap which needs to be bridged over in the interests of the small manufacturer and the domestic consumer alike before we can secure that economy in the use of coal which we know to be necessary. For it must be granted at once that our ordinary 16 candle illuminating gas is seldom an economical fuel at an average price of 3s. per 1000 cubic feet, though it is capable of being so used as to effect distinct saving under special circumstances. As an example of its economical use, even near the price stated, I may cite the case of the kitchen of St. John's College, Cambridge, where gas and steam have been substituted for coal, and an annual saving effected amounting to about £80. But in establishments which cannot be systematically conducted coal gas at 3s. is too expensive a fuel. Several solutions of this important practical problem have been proposed, one group of suggestions involving the supply of two distinct gases, an illuminating and a fuel gas, and therefore requiring two sets of street mains, but the progress of electric lighting is so rapid that gas companies would not be justified in outlay of capital on a second set of mains. Another proposal is to supply one gas of high calorific value but low illuminating power at a cheap rate, and this gas, when used for lighting, to be charged at the point of consumption with vapours of suitable hydrocarbons. But the true solution involves a compromise much on the lines along which gas managers are at present apparently working.

You are aware that the average produce of 16 candle gas per ton of coal is about 9500 cubic feet. By the introduction of steam to a small extent the volume of gas can be materially increased, but at the expense of the illuminating power. In order to compensate for this loss, rock or other oils are injected along with the steam, and the illuminating power is maintained. An objection to this practice is that carbon monoxide is present in such gas, but it is also found in many samples of ordinary coal gas, and provided the gas has a strong and characteristic odour, so that its escape can be readily detected, no risk need attend its use. The supply of the richer bituminous coals is steadily diminishing, hence the practice must grow of supplying a modified water gas instead of coal gas as we have hitherto known it. Better far, in the interests of producer and consumer alike, that the inevitable change in the character of the gas manufacture should be carried out with the full knowledge and assent of the public after due Parliamentary inquiry, and in such a manner as to secure the maximum advantage without undue interference with the great monopolies enjoyed by the gas companies. So many satisfactory methods are known by which the illuminating power of a gas can be increased at or near the burner, and gas as an illuminant is moreover being so certainly displaced by the electric light that the objections hitherto urged against the supply of gas of high calorific value but low illuminating power have almost ceased to have any practical force. On the other hand, the supply of a cheap gas of the kind I refer to would prove a great boon to small manufacturers as well as to the domestic consumer, and competent gas engineers inform me that no real difficulties lie in the way.

The rapid extension of electric lighting in our large towns brings us within measurable distance of some such sweeping change in the character of gas used, in its applications, and in its mode of employment, while the existing mains would serve for its conveyance, and comparatively trifling alterations in our domestic appliances would only be necessary.

It is in this direction, then, that the best prospect of solving a considerable part of the smoke fog difficulty seems to lie, and

it is in the same direction that we are to look for true economy in the use of coal. The completion of the system of electric lighting in towns is therefore to be desired by the community, not only on account of its great and obvious advantages for illumination, but because it will render possible the provision and distribution of a cheap gas for heating purposes, and the shareholders in gas companies of such fortunate towns should specially rejoice, as herein lies a good prospect not merely of maintaining, but of considerably increasing, their dividends. Gas companies would not only become purveyors of heat energy for domestic use, but for manufacturing purposes as well, not excepting the production of the electric light.

Hence, our duty to posterity and our own immediate interests coincide in requiring the use of more economical methods of using coal, and that which gives promise of the greatest number of advantages involves the conversion of coal as far as possible into gaseous fuel.<sup>1</sup>

I turn now from coal to peat, which is, as you know, a much less mineralized solid fuel. It is obvious that the question of peat utilization is one of much importance in Ireland, as nearly one-seventh of the island is bog. About 1,250,000 acres are mountain bog, and 1,575,000 acres are occupied by flat bogs, which occur over the central limestone plain of the country and stretch away to the north-west. This store of peat is an asset which may become valuable when you shall have exhausted your coal beds some 170 years hence. We would naturally desire to realize a portion of our assets at a much earlier date, as nearly all the coal used in Ireland must be brought from the eastern side of St. George's Channel. In this fact I think you have some explanation of the depressed industrial condition of the country, as manufactures involving the use of much fuel can only flourish in Ireland if the margin of profit be considerable, where the margin is small and competition keen (as in the greater industries), they must go under in the struggle with manufacturers having cheaper fuel at command. I grant it once that this is no adequate explanation of the absence of many chemical manufactures which do not involve large consumption of fuel, but it is the inevitable result in the cases to which my remarks apply.

Peat alone, however well prepared, compares very unfavourably with coal in several particulars.—

It is a very bulky fuel, in its ordinary condition occupying rather more than five times the space of an equal weight of coal.

2 It contains from 15 to 25 per cent. of water and seldom less than 10 per cent. of ash.

3 At least 2½ tons of average peat are required to perform the same work as one ton of average Staffordshire coal in ordinary fireplaces or furnaces.

Hence the general use of ordinary peat is attended by the disadvantages of requiring much greater storage room than coal, of producing a light and troublesome ash, and requiring more than thirteen times the bulk of coal to produce the same thermal effect. The last-mentioned consideration practically precludes its use in ordinary furnaces where heat of high intensity is required.

Now the force of the first objection to the use of peat, that of bulk, can be materially diminished by mechanical compression. Many excellent examples of compressed peat have been produced at various times, the most coal-like product I have seen being that of Mr. Hodgson, of Derrylea, who compressed, thoroughly disintegrated, and dried peat in heated cylinders, and by partially carbonizing under pressure secured the cementation of the material. Moreover, the ash of such compressed peat was not so bulky as that of the ordinary fuel.

I need scarcely say that the intensity of the heat obtainable with compressed peat is greater than with the loose material, but the actual thermal effect is not much altered, save in so far as the material is drier and therefore less heat is lost in evaporating moisture.

Extended comparative trials of coal and of good dense peat in steam engines have shown that the work done by one ton of peat was not more than 45 per cent. that of one ton of coal, hence if coal were 18s. per ton, peat could not compete with it under the most favourable conditions unless delivered at not more than 8s. per ton. Now the peat used in these trials did not contain more than 12 per cent. of moisture, but as dug from

the bog it seldom contains less than 35 per cent. of water, even when cut from a comparatively dry bog, it must then be stacked and air-dried. The present price of ordinary turf delivered at the bog is about 7s. per ton, when to this is added the cost of handling this bulky fuel, and carting for fifty miles, the cost exceeds 45 per cent. of that of coal even at inland towns, hence there is no real economy in the use of peat of the common kind in ordinary furnaces and grates instead of imported coal.

But the public are led by promoters of peat manufacturing companies, and others who should know better, to suppose that by certain processes of disintegration and compression peat can be made to approach very closely in fuel value to an equal weight of coal. There is no doubt that a better looking and denser product can be obtained by these means, and one which requires less storage room, but unless artificially dried as well, the actual heating effect of the fuel is not materially altered. I have no doubt that the cost of winning and treating the rough peat could be much reduced by the use of suitable labour-saving machinery, but all methods with which I am acquainted involving artificial drying as well as mechanical compression, have cost so much that the product could not compete with coal at the ordinary level of prices. As I have already said, the Irish peat forms a valuable asset, but one not capable of being realized on any considerable scale at present, at least when used as fuel in the ordinary way as a substitute for coal. But it is possible to so burn peat that it shall compare much more favourably with coal, and this solution of the problem is obtained by converting rough peat into gas.

You doubtless remember that in 1872 the cost of coal advanced even beyond the panic prices which prevailed for a week or two about the beginning of the present year. But the coal famine of 1872 lasted for a considerable time, and serious efforts were then made in Ireland for the utilization of peat. It soon became evident that the continuance of dear coal meant the suspension of several industries and their probable loss to the country, hence, leaving to others the attempts to convert peat into a suitable fuel for general domestic use, I took up the industrial side of the problem.

I saw that the best chance for economically applying peat for most manufacturing purposes lay in gasifying the material in a Siemens furnace, as two special and important advantages must obviously be gained thereby—(1) The use of peat in the rough state without artificial drying, (2) The avoidance of the injurious effects of abundant ash by burning the peat gas at some distance from its source, and under such conditions that the comparative value of coal and peat should be nearly in the proportion of their percentages of carbon. I therefore moved the Royal Dublin Society to appoint a committee of engineers and other scientific men to have the value of peat tested in the way proposed. The outcome was that the directors of the Great Southern and Western Railway of Ireland, acting on the recommendation of the able locomotive engineer, Alexander Macdonnell, C.E., decided to erect a complete Siemens regenerative gas furnace for working up scrap iron in their engine factory at Inchicore. This furnace was supplied only with rough peat, often containing as much as 38–40 per cent. of water, but no difficulty was found in keeping the welding chamber at a bright white heat for months at a stretch. The average consumption of fuel was 5.09 tons of peat for each ton of iron forged from scrap to finished work. Before the Siemens furnace was built the ordinary air furnace fed with coal was employed, and the average consumption per ton of iron was 4.96 tons of coal. I need scarcely say that peat is practically useless in such a furnace. Therefore peat used in the gas furnace as compared with coal in the ordinary welding furnace not only proved in practice to answer extremely well, but performed 97 per cent. of the work done by an equal weight of coal. As the price of peat was about half that of coal at the time, Mr. Macdonnell estimated that a saving of £47s. 9d. per ton of finished forgings was effected. If therefore the coal beds were exhausted we have a good substitute in peat for operations in which a very high temperature is required, provided the fuel is used in the gas furnace or according to some similar plan.<sup>1</sup>

The above remarks refer to work done twenty years ago. Now, thanks to the valuable investigations of Mr. Ludwig Mond, F.R.S., detailed in his Presidential Address of 1889, the pro-

<sup>1</sup> Since the above was written I have seen a short abstract of Mr. Valon's address to the Institute of Gas Engineers, in which I am glad to find that he takes a somewhat similar view of the situation to that expressed above.

<sup>1</sup> Of course the comparison is more favourable to coal when the latter is used in the Siemens furnace, as it is found that a ton of iron required an average of three tons of coal, therefore the work done by peat was about 60 per cent. of that by coal under the same conditions.

duction of ammonia from peat along with gas according to his method will probably pay for gasifying the fuel and materially facilitate the utilization of peat.

Much to my surprise and regret this work remains the sole practical outcome of our efforts in the direction of peat utilization during the fuel famine of 1872, so far as Ireland is concerned. Manufacturers now know how they can economically use peat for high temperature operations, and Dr. Bindon Stoney, F.R.S., has suggested that peat should be gasified at the bogs and carried to convenient centres of industrial activity. This could undoubtedly be done, especially if instead of 'producer' gas a fuel were manufactured approaching water-gas in composition, and such a gas of good calorific power can be manufactured from peat. Thus, as in the case of coal, peat could be made economically to provide light and heat energy as well for domestic use as for manufacturing purposes. Would that we could apply even a small portion of the energy stored up in peat to stimulate those who should be most active in utilizing in the best and most economical way the abundant material almost at their doors.

If, then, there are many and great advantages in converting our bulky solid fuels into gas and distributing them in that form for heating purposes or supplying power by means of gas engines, it is clear that such advantages must be confined for the most part to towns or special manufacturing centres unless the gases are condensed to the liquid form, and so rendered portable to considerable distances, but nature has already done a great part of this work for us in providing the wonderful material we call petroleum. I do not think 'wonderful' is too strong an adjective to apply to this material, whether we consider its nature, speculate as to its probable origin, or attempt to measure its value in the world's work, and in this, the concluding section of my address, I propose to sketch in broad outline the main points of public interest which relate to this, the most important of our liquid fuels.

The views of geologists as to the nature of the general process by which petroleum is formed are elaborately discussed in the eighth report of the United States Geological Survey, and the conclusions are there carefully summarized (page 506). In substance they are as follow—That petroleum is derived from organic matter by a process of slow distillation at comparatively low temperatures—that the organic matter was not in all cases of vegetable origin, but was in some instances derived from animal substances in contact with limestone, and, finally, that the stock of petroleum in the rocks is practically complete. It follows, of course, that the supply is exhaustible, but geologists do not even guess at its duration.

In contrast with all this is Mendelëff's view that petroleum is not a product from organic material, but is chiefly formed by the action of water at high temperatures on carbide of iron, which he supposes to exist in abundance within or below the earth's crust. The cracks and fissures caused by the upheaval of mountain chains permit water to reach the heated carbide at great depths, and carbides of hydrogen result in accordance with the general equation—

The hydrocarbides then distil up and condense within the cooler sedimentary strata. The occurrence of petroleum in active volcanic areas, as in Sicily and Japan, is held to accord with this hypothesis, which latter is also consistent with the remarkable fact that rock oil is usually found in the vicinity of mountains. But my chief reason for referring to this attractive hypothesis is that it permits us to suppose the hydrocarbides are still being formed within the earth's shell, especially beneath the geologically modern mountain chains, and that the supply of petroleum is practically inexhaustible. Whether that view can be sustained we must leave further evidence to decide, and now return after this digression to the consideration of the material itself.

The porous strata saturated with petroleum often lie at considerable depths below the surface soil of the district, and the oil is in many cases prevented from rising by a bed or shell of almost impervious material. In boring for the oil this enclosing shell is penetrated and the result often is the ejection of a column of liquid rising as a fountain of several hundred feet into the air. This violent expulsion of petroleum is due in great part to the pressure of pent up gases, and the crude liquid always contains some of these gases in solution. In some instances gas only issues, and a so-called

'gas well' is obtained, from which are emitted enormous volumes of marsh-gas and its lower homologues, as well as hydrogen. Some of these American gas wells afford from 10 to 14 million cubic feet per day, delivered at a pressure of as much as 400 pounds to the inch. Such gas is a fuel of high value and, as you know, has been largely utilized for industrial and domestic purposes at such great industrial centres as Pittsburg.

One million cubic feet of the natural gas obtained from the Trenton limestone at Findlay, Ohio, are said to do the same amount of work in heating as about 65 tons of Pittsburg coal. Some of these gas wells have been exhausted, but others have continued in full productiveness for several years. Although this natural gas is compressed and transported in cylinders to considerable distances, it evidently must remain of almost exclusively local value, not so the liquid petroleum which issues along with it or in its immediate neighbourhood. This is the most portable of all fuels obtainable in nature, and therefore is the most convenient means by which light and heat can be transmitted to all parts of the world—hence it is of greater practical interest to us than the natural gas.

You are aware that the hydrocarbides of which the American petroleum consists chiefly belong to the saturated group  $\text{C}_n\text{H}_{2n+2}$ , whereas those of Russian petroleum are mainly benzoid hydrocarbides of the general formula  $\text{C}_n\text{H}_{2n}$ , isomeric with the olefines, but really hydrogenized aromatic compounds of the naphthene series. Petroleum from both sources affords some of the lower homologues of marsh gas, hence in the process of refining crude petroleum by distillation the first products consist largely of butane, pentane, and hexane, which are separated and condensed by pressure, the product being used for refrigerating purposes, owing to its high volatility. Between  $80^\circ$  and  $120^\circ$  American petroleum affords a spirit of specific gravity about 0.75, and above  $130^\circ$  the illuminating oils are obtained, whose gravities vary about 0.8, while the residue which is not vaporized at  $300^\circ$  includes the heavier lubricating oils, which are also admirably suited for use as fuel, and are cheaper than those generally used for lighting purposes. During this process of refining by simple distillation there is always more or less decomposition in progress, hydrocarbides of high molecular weight being resolved into simpler ones at a comparatively high temperature, and when crude petroleum or its constituents are rapidly heated, this resolution can be carried so far as to convert a large proportion of the oil into permanent gas, valuable alike for illuminating and heating purposes. Thus petroleum is a fuel which can be permanently gasified with facility, and is no doubt wholly converted into gas just prior to combustion in our common lamps.

Several methods are employed for the conversion of oil into rich gas, and storing the latter for distribution through tubes in the ordinary way. In one class of such processes the oil alone is rapidly heated to a temperature of from  $800^\circ$  to  $1000^\circ$  in iron retorts, as in the methods of Pintsch and Keith, thoroughly described by Dr. Armstrong in vol. III of our Journal. The yield of gas seldom exceeds 130 cubic feet per gallon, as liquid hydrocarbides of low boiling points are condensed chiefly during the compression of the gas into cylinders for use in railway carriages. The gas is rich in carbon compounds, including methane, ethylene, and crotonylene, and its illuminating power, even after compression, is seldom less than forty-five candles. I may add that Mr. Ivison Macadam has given in vol. VI of our Journal (p. 199) a valuable series of observations on the gas-producing power of various oils treated by a process very similar in plan to that of Pintsch.

Another mode of converting petroleum into gas includes the use of steam, as in the process of Messrs. Rogers, of Watford, who inject the oil into red hot retorts by means of steam, the latter appearing to facilitate the permanent change of the petroleum without the formation of much carbon monoxide. The gas so produced is said to amount to about 140 feet per gallon of heavy oil used, and has, according to Mr. Rowan (this Journal, vol. VII), the following composition—

	Per cent.
Hydrogen	31.61
Marsh-gas	46.17
Illuminants	16.29
Carbonic oxide	0.14
Nitrogen	5.06
Oxygen	0.73

This gas is stated to have an illuminating power of fully 56 candles, and to lose little either by standing or by carriage to considerable distances.

As such petroleum gas has about 3.5 times the illuminating power of 16 candle coal gas, it follows that, so far as illuminating purposes are concerned, the gas producible from one gallon of oil by this process is equal to some 525 cubic feet of coal gas of 16 candle value. I shall later on refer to the heating value of this petroleum gas, but I have now justified the statement with which this section commenced, viz., that petroleum is virtually liquefied gas in a peculiarly portable condition. Hence in all states petroleum can be used as an illuminant as well as a fuel, whereas coal and peat can only be used as illuminants in so far as they can afford carburetted gas.

Let me now proceed to justify the further statement that petroleum is the most concentrated, and, on the whole, the most portable of all the natural fuels met with in considerable quantities.

Weight for weight the efficiency of liquid petroleum in steam-raising is much greater than that of coal. The estimates of relative value necessarily vary with different portions of the crude material used, and with the quality of coal employed in the comparative trials, hence some of the statements of results are often rather vague. Thus M. d'Allest found that one pound of refined petroleum evaporated 12.02 pounds of water, while only 6.5 pounds were evaporated per pound of a rather poor steam coal. The American results with crude petroleum and Pittsburgh coal give respectively 15 and 7.2 pounds of water per pound of fuel. Prof. Unwin has recently compared petroleum with Welsh coal in steam raising, the oil being injected by a steam jet through a highly heated coil and then burned perfectly with a clear flame. In his trials with a not particularly efficient boiler he found that 12.16 pounds of water were evaporated per pound of petroleum, and this result he considers about 25 per cent better than that afforded by the steam coal. These results agree with those of M. d'Allest so far as the effect of petroleum is concerned, but the coals compared were different in value for steam raising. Hence for an average coal the proportion is nearly three to two, in other words the practical heating effect of one ton of coal can be obtained by the combustion of only two-thirds of a ton of petroleum, while the comparison with the heavy oils would probably be still more in favour of liquid fuel. Petroleum has another advantage over coal in the matter of storage room, as one ton of the liquid occupies only four-fifths of the space of the same weight of coal, so that the bulk of the petroleum required to perform the same work in heating as one ton of average coal is little more than half that of the latter. It follows that a steamer constructed to carry 1000 tons of coal could, if provided with suitable tanks, carry 1200 tons of petroleum, equal in fuel value to about 1000 tons of coal. In addition, the liquidity of petroleum permits it to be pumped and conveyed long distances by gravitation in tubes so that its transport in bulk and in detail is easy. Therefore petroleum is not only a much more concentrated fuel than coal, but it is eminently portable as well and convertible with much greater facility into permanent gas. Against these advantages must, however, be set the inflammability of petroleum, and consequent greater risk of fire.

Now we have to consider the question of relative cost of petroleum used as fuel in liquid or gaseous form as compared with coal, the latter being our standard for reference as in the case of peat. We have already seen that about two-thirds of a ton of petroleum can do the same amount of work in heating as one ton of coal, therefore petroleum, when burned directly, cannot economically replace coal unless two-thirds of a ton of the liquid can be purchased for less than the cost of one ton of coal. We know the cost of ordinary lamp petroleum in these islands is at present far beyond that limiting value, even the heavy oils which are not good enough for lamps, and yet are too 'thin' for lubricants, only compare favourably with coal where the latter has to be carried long distances, and is therefore dear. However, all practical difficulties having been overcome in the use of these heavy oils for steam raising, a comparatively small advance in the general price of coal would at once render them economical for industrial use as fuel.

But when we compare petroleum gas with ordinary coal gas the comparison is much more favourable to the liquid fuel, unlike coal, petroleum is already more than half way on the road to conversion into gas. As you know, one ton of coal affords about 9500 cubic feet of 16 candle gas. On the other

hand, one ton of oil of sp. gr. 0.85 can afford about 24,000 cubic feet of gas, having an average illuminating power of 60 candles, or the equivalent of about 70,000 cubic feet of 16 candle value, and this rich gas admits of preparation on the small scale suited to country places, while the efforts used in the production of the gas can be heated by petroleum. The petroleum gas of some 60 candle power is said to be producible at about 6s. per 1000 cubic feet. If we were to assume that the calorific value of the gas is directly proportional to its illuminating power the cost would correspond to about 1s. 7d. per 1000 cubic feet of 16 candle coal gas. But the facts do not justify the assumption, as the calorific value of methane is known to be greater than that of the heavier carbides to which the high illuminating power is due, hence the comparison is probably less favourable to petroleum gas by about 25 per cent, though further experimental evidence is wanting on this point. However, even after this deduction, petroleum gas is the cheaper fuel as well as illuminant.

The necessary links between the elements of the trilogy on coal, peat, and petroleum are now, I think, sufficiently evident. If we desire to use each fuel in such a way as to develop most economically and conveniently its store of heat energy, we must first partially or perfectly gasify it. The newest member of the triad—petroleum—is the one which lends itself most easily and completely to such treatment, in consequence of its physical condition and chemical character. It is also the material that we must expect to facilitate the production of cheap gaseous fuels from coal and peat which shall at the same time possess sufficient illuminating power for most purposes. Chemical industries would probably benefit to a greater extent than others by the supply of cheap fuel of the kind in question, hence I have ventured to tax your patience by dwelling on this topic in your presence to day.

#### SUGAR-CANE BORERS IN THE WEST INDIES

MR. BLANDFORD'S report on sugar cane borers, published in the *Kew Bulletin* for July and August last, deserves more than a passing notice.

The report contains a plate of the insects in question, which will render their identification easy.

The first is a caterpillar and moth, *Chilo saccharalis*, the second a weevil, *Sphenophorus sacchari*, but the principal attention in the report is paid to the shot borer, *Xyloborus perforans*, a beetle which has lately caused considerable loss to growers of sugar canes in Trinidad. These losses have been so large that on some estates thirty per cent of the sugar crop has been destroyed, and in some fields fifty per cent, presumably by the devastations of this beetle.

This beetle *X. perforans* is to be found over a very large area in the tropics, it is the same species that has done so much damage to wine and beer casks, it has been found in India, the Malay Archipelago, Madeira, Mauritius, North and Central America, Brazil, Guiana, Peru, and probably in Australia, so that no sugar-producing country can consider itself free from the fear of its ravages.

Mr. Blandford's report is interesting and valuable, not only for the amount of information it gives relative to this most destructive insect, but also for the way in which he points out what remains still to be investigated on the subject, so that it not only furnishes valuable information to the planter in the West Indies, but also tells him what course his further investigations should take, and it might well serve as a model to future observers in drawing up similar reports.

"The chief subject for investigation," to quote Mr. Blandford, "is the relation of the insect's attacks to the health and condition of the canes, whether it (the shot borer, *X. perforans*) is a true destroyer, or merely a follower and manifestation of antecedent and more serious injury." This question, Mr. Blandford says, "I do not attempt to solve, it can only be studied in all its bearings by observers on the spot," and he further gives a list of definite points which require inquiry and solution.

There is no doubt that the presence of *X. perforans* is usually accompanied by the sugar-boring caterpillar, *C. saccharalis*, and the weevil, *S. sacchari*, and also with fungoid growths, which may of themselves account for the acidification of the juices of the cane, which is apparent in canes attacked by the shot borer, but whether or not the shot borer attacks healthy canes is a question on which there is much diversity of opinion, and we hope that bringing the question before our readers will lead to

more observations and experiments to decide this important question, as "while there is no proof, there is a strong presumption that *X. perforans* cannot begin the attack." Still there is much difference of opinion, as the Trinidad Commission, which investigated the subject, "believes that the beetle is the primary cause of the disease, and that it is immaterial whether the cane is healthy or not," others believe that it is only canes which are "already physically weakened by other causes which are attacked by it."

The Transparent Cane and Caledonia Queen enjoy an entire immunity from the attack, "even when growing side by side with badly infested Bourbon canes, and varieties raised by seed show no signs of being attacked." It is therefore suggested that perhaps the Bourbon cane, enfeebled by long cultivation on the same lands and degenerated by careless ways of propagation, has become powerless to resist the attacks, and planters in their investigation must consider the possibility of attacks "being favoured by constitutional weakness which in no way implies want of care in cultivation, but perhaps the reverse."

The enemies of the shot borer are still to be found.

An important lesson taught by this report to the planter is the necessity of varying the description of canes grown and the great value of the new seed canes raised in Barbados.

### PARIS

**Academy of Sciences, Sept. 19.**—M. Duchautre in the chair.—On the white rainbow, by M. Mascart. This phenomenon, usually known under the name of Ulloa's circle, is explained not on the untenable assumption of water vesicles, but of very minute drops as constituting the mist upon which it is seen. The diminution of the diameter of the drops causes a displacement of the first maximum of the interference fringes which produce the supernumerary arcs. The relative intensities of the various colours retain equal values long enough to make the rainbow appear achromatic, with perhaps a slight red coloration along the outside. The radius of such a circle has been known as small as  $33^{\circ} 30'$ .—Observations of the new planet Wolf (1892, Sept. 13), and of the planet Borrelly-Wolf (Bri-gone?), made at the observatory of Paris (west equatorial), by M. Bigourdan.—On a recurring series of pentagons inscribed to the same general curve of the third order, by M. Paul Serret.—On the production of the spark of the Hertz oscillator in a liquid dielectric instead of air, by MM. Sarasin and De la Rive. The two balls of 3 or 4 cm. in diameter between which the Ruhmkorff discharge takes place in the Hertz oscillator, were plunged into an insulating fluid. This was, in the first place, olive oil, contained in a cylindrical vessel, 20 cm. in diameter, pierced laterally to admit the end branches of the oscillator. Sparks 1 cm. long were obtained, giving a characteristic sound, louder than that of a discharge through air. The effect on the resonator is notably increased by the arrangement, most brilliant sparks being produced. The interferences of the electric force by reflection from a plane metallic surface give the same results as in air. During the discharge, the oil is carbonized and loses its transparency, but without affecting the intensity. Similar experiments were made with essence of terebenthine and petroleum, but the oil proved the safest and most advantageous medium.—The action of bromine in presence of aluminium bromide on the cyclic chain carbon compounds, by M. W. Markovnikoff. It has been shown that a small quantity of bromide or chloride of aluminium added to the bromine produces a vivid reaction with the carbon compounds of the aromatic series, usually resulting in substitution products of a crystalline form. Further experiments show the generality of the reaction for all the hydrocarbons of the series  $C_nH_{2n}$  which were examined. It has been studied chiefly as regards the naphthene (hexacarbon) series, and may be expressed by the general equation—

The rule seems to be that the action of the bromine on the naphthenes at the ordinary temperature takes place principally on the hydrogen atoms of the cyclic chain, transforming them into benzene nuclei, in which all the hydrogen atoms are replaced by bromine, whilst the lateral chains remain intact. It is found that besides the bodies of the aromatic and naphthene series, the hydrocarbons of the paraffin series also react easily in presence of  $AlBr_3$ .—The rotatory power of fibroin, by M.

Leo Vignon.—Experimental researches on the bulb centre of respiration, by MM. J. Gad and G. Marinresco.—Influence of continuous and discontinuous electric light upon the structure of trees, by M. Gaston Honnier. Out of three lots of plants, one was submitted to a constant electric illumination, another to an illumination alternating with twelve hours' darkness, and a third was left to develop in ordinary daylight. The experiments were carried out in the electric pavilion of the Central Markets at Paris. The temperature was pretty constant (between  $13^{\circ}$  and  $15^{\circ}$ ), the light was given by arc lamps in shades, and the trees—pines, beeches, oaks, and birches—were surrounded by glass, the air being gradually renewed. It was found that continuous electric light produced considerable modifications of structure in the leaves and shoots of the trees. The plants breathed, assimilated, and secreted in a continuous manner, but they appeared as if encumbered by this continuity, and showed a simpler structure. The shoots were very green, the leaves more open, less firm, and smaller. Differentiation was less decided in every respect. In the specimens exposed to intermittent illumination the results were very similar to those obtained under normal conditions.—On the discovery of the line of no declination, by M. W. de Fonville. From an inspection of geographical maps preceding or contemporaneous with the discovery of America it appears certain that Columbus was the first to discover the variation of the compass. Indeed, it was the rapidity with which the observed declination diminished which produced consternation among his seamen, whom he could only save from a panic by persuading them that the pole star had changed its place, while the needle remained a true guide. The stratagem succeeded, but Columbus suspected that the radius of curvature of the earth was different at the Sargasso sea, and that the line of no declination represented a natural frontier between the territories of Europe and Asia. This natural frontier was adopted by the Pope Alexander VI. in his division of the new world between the rival aspirants. Columbus himself found that the line did not coincide with a meridian during his third voyage, but the illusion guided even Magellan, and was only dispelled by Halley's magnetic chart in 1700.

NATURAL SELECTION AND ALTERNATIVE  
HYPOTHESES

*Animal Coloration: an Account of the Principal Facts and Theories relating to the Colours and Markings of Animals.* By F. E. Beddard, M.A., F.R.S. (Swan Sonnenschein & Co.)

THE theory of natural selection has been pre eminent for over thirty years as the most generally accepted explanation of organic evolution. It has, and has had throughout, many critics, but its position is strengthened by the fact that these critics invariably accept the principle as accounting for something, while most of them make it clear that they reject all other proposed substitutes, except those for which they are individually responsible. Sometimes the attempt to formulate an alternative hypothesis, or to apply it to the facts of nature, breaks down as soon as it is undertaken. A curious instance of this is to be found in Semper's "Animal Life," which begins with very large anticipations—all the "popular cant" of the Darwinian is to be "put out of court as useless", a selective explanation can never be a real one, but for the latter we are to consult the subsequent pages. But as case after case is examined, the author is constrained to admit that his real explanation is not forthcoming, and that, although he never will think much of selection, it is the only cause he has to offer. Semper would appear to have written his preface before he considered the materials from which he proposed to write his book.

Mr. Beddard's work does not open in this ambitious manner, but he is far bolder in offering alternatives to natural selection, and in applying them. Further consideration would probably have brought him to Semper's admission, at least as regards many of his suggestions. Indeed, the number of these suggestions, and the confidence with which they are brought forward, are clearly due to haste and want of sufficient reflection, which also leave their mark upon the scheme of the volume and the number of contradictory statements to be found in it. Nor is this to be wondered at when the amount and variety of work which the author accomplishes is borne in mind. But the result will be to confuse the beginner and the untrained student. Principles which are supposed to be refuted in one part, are subsequently introduced with considerable enthusiasm as the heads of the main sections of the work, and are later on again treated with scant courtesy. In fact some readers will rightly infer that the author is a profound sceptic as to the value of the scheme he nevertheless adopts. Others may perhaps be led to suppose, by the arrangement of the book, that the author is sceptical of his own scepticism. Even the very fairness of the author in giving the arguments in favour of views he rejects, will be, such is the system pursued, a cause of confusion to a reader. These sources of difficulty are not only apparent in the general scheme, particular explanations are disputed in one part, and adopted a little further on without a word of explanation.

The chief value of the book lies in the fact that it is

straightforward, and speaks out on points of great difficulty and dispute. Arguments of which echoes have been already heard, perhaps, in the report of some conversation which is supposed to have taken place, or which have been crudely stated in the publications of unknown writers, are here met with in a form in which they can be dealt with. For thus stating the opinions which are vaguely supposed to be held, perhaps vaguely held, by others, every Darwinian owes a debt of gratitude to the author.

The main aim and purpose of the book would appear to be a criticism of natural selection as applied to the explanation of the colours of animals, and the proposal of alternative explanations.

Some of the difficulties which the author finds in the theory of natural selection appear to follow from his conception of the process itself. Thus, on p. 12, he speaks of polymorphic species appearing in two or more well marked forms, and of those extreme cases of variation known to entomologists as "varieties," and concludes, "In fact, if colouring were really constant for a given species, there would be no chance for natural selection", thus implying that natural selection depends upon such pronounced divergences, instead of upon those minute differences which distinguish the individuals of every species. He then continues, "Supposing that a marked variety occurs in a wild species, there is, first of all, a considerable chance against its reaching maturity, secondly, there is a considerable chance against its finding a mate, thirdly, the hereditary influences on both sides are against the perpetuation of the variety. These appear to be more potent causes of the comparative fixity of colours in wild animals than the unfitness of the varieties to live." It has already been pointed out that the "marked variety" is of little importance for natural selection as compared with the individual difference. But if the objections urged were valid there would appear to be little chance of a "marked variety" existing in any numbers and persisting from generation to generation, side by side with the normal form, and yet numbers do persist. As to the first of the alleged objections, the chances are against every individual, but not equally so, if there be anything in natural selection. So far from this objection being valid, it is but the expression of a fact upon which natural selection rests, the fact that many more individuals of every species are born into the world than can by any possibility survive. Were this not so all selection would cease. The second difficulty certainly does not apply to minute individual differences which occur in vast numbers. To take the simplest case, let us suppose that the individuals of a species are divided, as regards any character, into two equal groups—the one above, the other below the mean. It is clear that each individual would stand as good a chance of mating within the limits of its own group as within those of the other. The third objection does not appear to me to hold in the case of "marked varieties" any more than with individual differences. The total hereditary influence of the varying side, allowing even considerable force for atavism, is certainly in favour of the variation. Furthermore, experience shows us that among the offspring will be some that vary even further than their parent. Those

who accept the Darwinian principle do not expect heredity to achieve more than this—to offer the materials which can be accumulated by natural selection.

Interesting as is the study of such "marked variations" and the statistics of their occurrence in nature, the great principle of natural selection, whether applied to the evolution of animal colouring or to any other character, is not greatly affected thereby, but rather demands such exact numerical investigations as those published by Galton upon man, by Wallace upon various animals, by Weldon upon *Craugon*, and by Lloyd Morgan upon bats.

Another objection to the natural selection argument is given on p. 25, and it too turns on the author's conception of the mode in which this principle operates. Recapitulating Weismann's argument that longitudinal stripes have been replaced by oblique ones in certain *larvæ*, on account of the more perfect concealment afforded by the latter, he points out that some species "have, on the contrary, remained at a stage of coloration which is, *ex hypothesi*, disadvantageous." The longitudinal striping was never disadvantageous, but only relatively less advantageous, in certain species, and under certain conditions. The failure of a species to take this line of evolution may have been due to many causes, the development of other modes of defence, the nature of its peculiar environment, or may be solely due to the kind of selection exercised by its foes.

The author sees far-reaching conclusions against the principle of natural selection in the admission that pigment as a cause of colour was originally non-significant, and is so still in many cases (colours of certain lower forms, colours of blood, fat, &c.). He argues (pp. 68-70) that as colour did not arise by natural selection, it must be a normal product of the organization, and its disappearance in cave-dwelling forms cannot be due to the cessation of selection, but must follow as the direct effect of surroundings, although he does not even hint at the mode in which such effects are supposed to be wrought. But these conclusions are by no means warranted by the original admission. The first appearance of pigment in the skin of the ancestor of a group of species which are now coloured was certainly a normal product of the organization, but the fact that this variation subsequently spread over all the individuals of the ancestral species, and of those to which it gave rise, will be claimed by Darwinians as the result of selection. And so strong are the tendencies of variation in other directions that partially or completely albino races can be produced by man in a relatively short period of time, while such individuals are far from uncommon in nature in spite of selection. The facts support the opposite conclusion that the absence of colour from the skin would be the normal result of organization for the average individual, were it not for the strong and continuous action of selection. There are other instances of the disappearance of colour in addition to that which has occurred in caves, and in some of these the conclusion appears inevitable. The whiteness of birds' eggs laid in dark holes certainly cannot be traced to the direct action of surroundings, any more than the colour of eggs laid in open nests, and natural selection being prevented by man, the colour is

disappearing from the eggs of the domestic fowl, just as it is lost in other species when prevented by darkness.

It is certainly true that colour "must be there before it can be acted upon, and modified in this or that direction according to the needs of the animal." But this objection, which has been familiar since the earliest days of natural selection, is less formidable than it appears to be. Colour must have been present in the skin of some individual ancestor certainly, but its *existence*, as well as its modification, in the normal individual of the species is to be explained by selection.

It is hardly necessary to point out that this argument does not apply to colours which still remain non-significant and are excluded from selection, but these are precisely the colours which are unaffected by the changes of environment alluded to above, the blood of cave-dwelling vertebrates remains red like that of others; the yolk of eggs laid in holes does not differ in appearance from that of those laid in open nests.

A similar argument as to seasonal change of colour in arctic animals may be answered in the same manner.

The author's difficulties appear to arise in part from his inadequate conceptions of the struggle for existence. Speaking of certain night feeding caterpillars, he says (p. 102) "It may be suggested that they prefer to feed early in the evening, when their colours, if conspicuous, would be readily seen. If this is so, it does not much matter, for the birds would—the bulk of them at any rate—have gone to roost." Or speaking of *Mimnoneutes*, an Amphipod crustacean which bears a remarkable likeness to a *Medusa* well defended by stings, he objects to attribute any significance to so wonderful and detailed a superficial resemblance, because "a school of whales or a shoal of pelagic fish, rushing through the water and devouring all before them, could hardly be supposed to stop and analyze carefully the advantages or disadvantages of selecting or rejecting a given animal as food." On p. 115 he remarks "If Mr. Poulton is right in assigning a protective value to the bright-coloured wings of butterflies, 'as a conspicuous mark easily seized by an enemy, and yet readily tearing without much injury to the insect,' it seems unnecessary to pay much attention to the supposed utility of protective colours, such as are shown by the *Kallima* or the Green Hairstreak."

The author scoffs at natural selection as an "easy" road to an explanation, as "the very simple hypothesis of a need for resemblance to the environment." It may at any rate be maintained that this method of meeting it is very far from profound.

It is only possible to give a very brief account of the causes which the author would propose to substitute for natural selection. The merits of each proposal lie in its application, and the consideration of this means a discussion of each particular case.

In support of the "effects of food upon colour," a number of examples are quoted, many of which are so inherently improbable and so imperfectly supported by details, that it is impossible to accept them as evidence. I am very far from disputing that changes of colour may be directly produced by certain foods, although the significance of such changes in the evolution of animal colouring is a very different matter. When the author proceeds to

apply this principle he falls into errors which a little consideration would have avoided. Thus, on p. 21, the following sentence occurs—"Seeing that pigment has been proved in so many cases to be alterable by changes in the food, it is not surprising to find that as a rule the colours of larvæ are totally different from those of the adult form," implying that the difference of diet accounts for the difference of colour,—a conviction stated even more strongly on the next page. It is quite sufficient answer to this hasty conclusion to point out that the colours of the imago are just as dependent on the larval food as the larval colours themselves, and that they have made their appearance long before the imago has had the opportunity of feeding. Again, in speaking of the "strong superficial likeness" of the Drone-fly (*Eristalis tenax*) to a bee, the author hints at likeness of food as a possible explanation (p. 232). "It is an interesting fact, in connection with the resemblance between this fly and a hive bee, that it feeds upon pollen and honey. This fact may have some significance in relation to the effects of food upon form and coloration." But the form and coloration of *Eristalis* depend upon the food absorbed by its "rat-tailed" larva, living in putrid mud, under conditions utterly unlike those of the larval bee.

Under the consideration of light as a cause of colour an extremely bad piece of reasoning is adopted from Werneburg (p. 62), who argues that light has an important influence on the formation of pigment during the pupal period. By selecting favourable instances and describing them with an enthusiasm which borders on inaccuracy (e.g., speaking of *U. sambucaria* as "bright yellow") and by neglecting all others, he makes it appear that there is something to be said for this view.

In the section on "Variable Protective Resemblance in Chrysalids," the results of recent work are given very inaccurately, the golden colour of pupæ is explained as due to "thin films of air or some gas," and it is even suggested that "intense light may cause some gas to be given off in greater abundance." But it was shown years ago that the appearance is due to some lowly refractile liquid, and, in fact, alcohol answers the purpose very well indeed. Gases do not appear to have the power of entering the intervals between the cuticular lamellæ, perhaps because the latter come together and obliterate the chinks on the evaporation of the fluid. Again, it is stated that "the pupa was also made to assume a light colour upon one half and a dark colour upon the other." As a matter of fact the invariable failure of the pupa to do this formed the basis of some of the principal conclusions reached. It was also surely unnecessary to quote an ignorant assumption of Eimer's on the subject—an assumption which was not even original, and has been disposed of long ago.

In favour of the effects of climate reliance is placed on Scudder's conclusion that melanism is only found in the butterflies south of New York, albinism only to the north (p. 55). And yet in Europe melanism is especially prevalent among the northern moths, from which we may infer that the American observations, however they are to be explained, are not direct effects of climate.

He suggests that the blackness of a lizard on one of the Canaries may be due to moisture, but these islands

are about as dry as small oceanic islands can be. All the lizards seen by the present writer in Tenerife and Grand Canary, some three or four species, were dark in colour and harmonized with the tint of the dark dry volcanic rocks on which they were seen, and among which they almost invariably escaped when pursued.

One suggestion is very remarkable. After giving reasons why he does not consider that the resemblance of *Volucella* to humble-bees, &c., is to be explained as a case of aggressive mimicry, the author suggests (p. 228), "If wasps and bees have the same unintelligible liking for keeping pets that another group of Hymenoptera—the ants—have, the whole series of facts may prove to have a very different meaning, but one which is not quite in accord with the theory of mimicry on the part of the *Volucella*." The keeping of pets by ants is so very far from being unintelligible in some of the most important cases (*Aphides*, Lycenid larvæ, &c.) that we may fairly expect an explanation in other instances. But even if the author's suggestion were valid it would still fail to account for the very point at issue—the great superficial resemblance of *Volucella* to Hymenoptera.

On p. 92 he is quite prepared entirely to dispose of all advantages in the struggle for existence in favour of fertility, this alone is enough to prevent extermination. Speaking of the wonderful disguise of Geometer larvæ (and if this be not the result of selection it must be admitted that the principle fails indeed) he says, "In the meantime the excessive fertility of the parent moths appears to be a sufficient guarantee against extinction, apart from any subsidiary advantage to be gained by colour protection." It is sufficient reply to this statement to point out that the fertility of these small-bodied moths is very far from excessive when judged from an insect standard, that if the larvæ are offered to any insect-eating animals they are when detected, devoured with the greatest avidity, but that if offered motionless on their natural food-plant they are often passed over, that insect-eating animals, especially when rearing their young, are by no means fed to repletion, so as deliberately to refuse the food they evidently relish.

It is very confusing after this candid avowal to read a few pages further on (p. 97), "On the whole, it seems more profitable to a caterpillar to adopt protective resemblance to its surroundings as a means of escaping its foes, at any rate, this is what actually occurs. 'The main purpose in life of a caterpillar,' says Mr. Scudder, 'next to feeding, is not to be seen.'"

Many quite irresponsible suggestions, which it would have been wiser to have withheld unless accompanied by at least some evidence, are made or adopted from other writers. Of this nature are the remarks of Leydig on the colours of *Helix nemoralis*, and the author's suggestion that the dark variety of the female Silver-washed Fritillary may be due to the moisture of wooded districts.

Of some of the author's suggestions we may use his own words, and say, "This explanation has an air of reasonableness, which might lead to the inference that it had been amply tested by actual experiment" (p. 64). Others however, including some which have been quoted here, certainly appear to lack this "air of reasonableness."

The author is especially candid and straightforward in bringing forward the evidence in favour of an explanation he is about to attack. After thus fairly showing the strength of the opposed position, he proceeds to reject it for reasons which will strike the instructed and uninstructed reader alike as singularly inadequate. Examples of this method occur continually throughout the volume. As an example may be selected his treatment of the opinion that the light of phosphorescent organs enables certain deep sea animals to see. He admits the existence of eyes, the prevalence of phosphorescence, the intensity of the light emitted, the existence of "lens-like transparent bodies serving to concentrate the rays of light," the fitness of the light to illuminate the prevalent colours. In spite of all these facts the author believes that all deep-sea colours are unseen and meaningless for the following remarkable reason—"The presence of well-developed eyes, or the total absence of these structures, are, as has been explained, intelligible on the theory of abyssal light, not so the existence of eyes in an intermediate condition. The inevitable conclusion, therefore, from these facts appears to be that the brilliant and varied coloration of deep sea animals is totally devoid of meaning, they cannot be of advantage for protective purposes, or as warning colours, for the simple and sufficient reason that they are not seen" (p. 37). The author carries this conclusion to its logical end, and, pointing to the resemblance of deep-sea forms to their shallow-water allies, and the existence of protective resemblances in both, he maintains that "if natural selection has been the cause in the one case, it ought to be in the other."

The question therefore is pressing: need natural selection be responsible for the coloration of the shallow-water forms? (p. 38). A somewhat large conclusion to base on the fact that the eyes of certain deep-sea animals are in process of degeneration! The author admits that the *absence* of eyes is no argument for his views, and yet, in every such instance, a gradual process of degeneration has been passed through. He gives us no reasons for rejecting the opinion that the cases upon which he bases such startling conclusions are merely tending in the same direction, indeed, elsewhere (p. 11) he insists on the probability that such biological changes are still progressing. It is indeed most probable that light is far from widespread or intense on the floor of the ocean, and that, therefore, eyes to be of use must be unusually efficient, while, unless absolutely necessary, they are likely to disappear. We meet, in fact, with a case somewhat parallel to that of beetles on oceanic islands in tempestuous zones, where selection operates in opposite directions—towards unusual powers of flight, when flight is a necessity, and towards the total loss of any such capacity when it is unnecessary. Thus, among deep-sea fish we find eyes of immense relative size, as well as those which are degenerate. And the phosphorescent organs of certain fish (*Cerattus*) appear to emit a light which is invisible to the degenerate eyes of the possessor, but serves to attract other and better endowed fish upon which the *Cerattus* feeds. The frequency of this degeneration among the deep-sea Crustacea, which impressed the writer so profoundly, may very probably be due to conditions of life which render vision less necessary for them than for many

other groups, and this is especially probable since many shallow-water genera are sightless, as is abundantly shown in the book itself (p. 36).

On pages 115, 116, the author adopts Prof. Weldon's objection to the usually received interpretation of the whiteness of certain eggs, and the under-sides of fish, porpoises, &c., which are seen from below, on the ground that snow-flakes appear almost black when seen from beneath against the bright sky. The original suggestion is due to neither Mr. Wallace nor to the present writer, but to Erasmus Darwin, writing very nearly one hundred years ago. The objection entirely misunderstands the hypothesis, at any rate so far as the eggs are concerned. If an egg, lay exactly over one of the interstices in the nest, it would, of course, shut out the sky altogether, and when viewed from some distance through the opening would appear dark like the nest itself. There would be no question of its appearing against a back-ground of sky. As a matter of fact, no such continuous back ground can be seen through the nest at all. Minute bright points are seen through the interstices of the nest, and those of the leaves and branches above and below it. The hypothesis in question suggests that part of the bright white side of an egg, viewed obliquely from below through an interstice, may be mistaken for one of these bright points. The hypothesis may be erroneous, but it is not to be set on one side by a criticism which fails to understand it. In the case of the fish, the question is complicated by the absorption of light by the layer of water.

The reader who finds that the above-quoted criticism is held to be destructive by the author, may be excused strong language when he meets with the following sentence only seven pages further on—"Among pelagic fish it is common to find the upper surface dark-coloured and the lower surface white, so that the animal is inconspicuous when seen either from above or below."

The chapter on Warning Coloration is one of the most valuable parts of the book, for in it we meet with a solid contribution to the subject in the form of some interesting experiments conducted by the author upon the animals in the Zoological Gardens. Many of the results are of extreme interest, and are a further proof of the difficulty of the investigation, and the great care with which it must be conducted if the conclusions are to be depended upon. It has been already suggested that some of the results may be perhaps explained by the fact that the insect eating animals chosen for experiment are restricted to a very monotonous or very scarce insect diet. In some rather extensive experiments made by the present writer upon a marmoset, it appeared that the animal possesses a most keen appreciation of the meaning of warning characters, but the individual in question was accustomed to be fed on a very varied diet. The discussion of the details given in this chapter cannot now be attempted, but it may be safely affirmed that there is nothing which is fatal to the theory of warning colours, when we admit, as we are of course bound to do, that even unpalatable animals have their special enemies, and that the enemies of palatable animals are not indefinitely numerous.

Further criticism of the arguments is rendered impossible on the present occasion by the exigencies of space. Certain obvious misstatements call for correction, such as

the description of the jet black larva of the Peacock Butterfly as "dusky greenish" (p. 21), the assertion that the present writer discovered uric acid in the excreta of *Vanessid* imagoes (p. 41), the implication that leaf-mining larvae eat only the deeper tissues of the leaf instead of everything between the upper and lower cuticle (p. 63), the description of "red eye-like markings upon the blue underwings" of the Eyed Hawk Moth (p. 134), in which red and blue should of course be transposed.

The book is well printed, misprints such as "Lortrix" for "Tortrix" (83), "freshly-moulded" for "freshly-moulded" (67), "distinction" for "distinctive" (185) being fortunately uncommon.

The coloured plates are good, although it would have been a pleasure to see the wings of one of the resting *Volucella* in Plate IV folded one over the other in a very characteristic attitude. The antennæ of the *Kallima* shown at rest in Plate II would have been concealed, and the same applies to the figures of the Buff tip and Lappet Moths. The worst figure is that of the Bee Hawk Moth on p. 245, in which an entirely wrong notion of the opaque border to the wings is conveyed. The source of the figures is not mentioned.

EDWARD B. POULTON

### SUNSHINE

*Sunshine*. By Amy Johnson, L.L.A. (London: Macmillan and Co., and New York, 1892.)

THIS book is likely to puzzle any one who may by chance pick it up and glance casually over the pages, more especially if he should happen to first open it towards the end and find two chapters headed "Tommy's Dream," concluding with a conversational account of how "the nurse puts baby into a bath, generally too hot or too cold, and scrubs away as if he were a wooden doll. Poor baby's skin is red all over, and he screams with pain," &c. On the other hand, in the early part of the book, several familiar figures, such as pictures of ice flowers, or diagrams of the action of simple lenses, of total reflection, of the rainbow, &c., show that "Sunshine" is, in spite of the nursery episode, in reality connected with physical science. As a matter of fact the authoress has taken a number of easy experiments and every-day observations, and has amplified and explained them in a simple and often very charming manner, adopting for the purpose the conversational form as between herself, called teacher, and, judging by the number of Christian names of the children addressed, a host of youngsters.

The conversational style is out of fashion just now, but no objection can be taken on that account. What is of far more importance is the general effect produced upon the mind of the child. The writer of this notice well remembers how the attempt was made to beguile him into being interested in conversations between a horridly precocious child Willie and his papa. Willie always said the right thing, and always made the right mistakes, so that much instruction was to be gathered from the answers and corrections of his papa. The

writer, no doubt, did acquire some general information, perhaps he did not resent the attempted deception, but he is sure that he would like to have punched Willie's head, or to have made him suffer in some way that is pleasing to the boyish imagination. In the present instance the risk of arousing open hostility on the part of children who may receive instruction from the pages of "Sunshine" is largely reduced by the fact that the conversation is very one-sided, the children are made to say very little in these talks—they are not quite lectures, but more lectures than conversations. Whether "teacher" says too much, or in the attempt to appeal to the imagination rather than the reasoning faculties of her audience rambles too far afield, is a question of taste. Many parts of the book demand the highest praise, though in some the authoress seems to have gone beyond reasonable bounds. For instance, after a most clear and excellent illustration of the method by which the distance of the moon from the earth is determined, in which the children are made to find by folding paper how far it is from the table to a ball hanging up in the room, the imagination of the reader is stimulated as follows—

'At the beginning of our talk about the moon, I tried to impress upon you what old travellers you were. Do you remember how far you have been each year? (585,000,000 miles) And you, Tom, are—?' "Seven." "What age are you, Percy?" "Eight." "And you, Minnie?" "Nearly eight." "You shall work that sum out for me on your slates. We will neglect the travelling since last birthday. Multiply 585,000,000 by 8, Percy. Four thousand six hundred and eighty millions of miles, you say. Have you felt any pain or sickness? Are you willing then to accompany me for a little 'out' to call on our next neighbour, the moon? It is only 240,000 miles, and would take us a little over three hours and a half at earth's usual rate of travelling. Do you think your mothers would trust you with me if I guaranteed to bring you safely back again? Most of you say 'Yes.' What is it that Ethel is saying to you, Lucy?" "She wants to know if we are really going, or if it's 'only pretending.'" "That is a question which Ethel must decide for herself. Those who are going with us must be ready in time, or they will be left behind. Before we make a journey it is usual to consider, not merely the distance, but a few other matters also, such as—'What to take with us,' 'How long we shall be away,' 'Where we can get lodgings,' 'Whether we should take shawls, umbrellas, &c.,' and so many other considerations, that I am afraid we can't go to day. Make all inquiries at home, and let me know how many of you are prepared to go."

As has been stated, the imagination rather than the reason is being constantly appealed to, and for the purpose the most picturesque language is employed. Perhaps the most striking example is to be found in a chapter headed, "The Mill with Stained Glass Windows." A beam of sunlight is made to pass through a condenser and into a slit. Then slips of coloured glass, red, green, and violet, are placed edge to edge over the slit, and the red-green-violet line of light is looked at through a scratch in a piece of smoked glass. The resulting diffraction phenomenon is the mill with stained glass windows. The upper story with violet windows has a greater number closer together than the second story with the green windows, and there is the same difference between this

and lower story with the red windows. From this result by a simple step the coloured bands seen when white light is employed are readily explained. Of course, and wisely so, no attempt is made to explain why with monochromatic light the windows are seen at all. In the same manner most of the phenomena described or which can be observed by following the clear and simple directions are stated to be what they are, rather than proved or explained. The authoress, guided by her own experience as a school-mistress, is probably right in continually pointing out fresh phenomena of interest, which may or may not be immediately forgotten, rather than in wearying the child with difficult arguments which could at best be imperfectly understood, and which would be sure in many cases to awaken a feeling of disgust. In short, *Sunshine* is a kindergarten and not a school.

Simple and homely language is employed with the greatest propriety, but occasionally it tends to be vague or even to produce a wrong impression. One or two actual mistakes may be referred to in order that they may be corrected in a future edition.

Thus, it is stated that as a rainbow entirely vanishes when the sun is as much as 42° above the horizon we can never see one at noon. "In the summer" should obviously be added. The reader is told to spin a top carrying a disk painted half yellow and half blue and he will see green. There is a confusion here between the colour obtained by adding two colours as by spinning, and that which is the result of mixing pigments. As is well known, green is not produced under these circumstances, but white or nearly white. The four chapters on soap bubbles, which contain much that is sure to please, are supplemented by some special instructions, which, however, are not quite correct. Fig. 167 is an illustration of an experiment purporting to measure the surface-tension of a soap bubble by the depression of the water level in a quill tube dipping into a glass of water. As the bubble is drawn much larger than the two hands, the pressure within it would not produce any depression of the water below the general level. It would not even visibly affect the capillary elevation. Then it is stated that the surface tension of pure water is 16.62 grains per square inch. It is, as a fact, a little over three grains per linear inch. The confusion becomes greater in the passage, "We know exactly how much energy it (the elastic film of water) has—16.62 grains per square inch. A tube of 1-inch bore will lift up 16.62 grains of water."

There is one serious fault in the book. Serious because an experiment is described as though it were being performed to an audience which is not only impracticable and impossible, but which would require in a soap-film a property different in kind to that which it possesses. A school-slate frame with one end removed is hung up so that the remaining end is uppermost. A knitting needle is cut of such a length that it will slide freely in the groove made to hold the slate. From the knitting-needle a pill-box is hung by threads. The object is to weigh a letter. A soap-film is spread over the frame as far as the knitting-needle.

"See how the film is stretching, the knitting-needle is bringing it down like a blind. Now we place a letter in

the balance. I know that it weighs just half an ounce, so I can mark on the slate-frame with my blue pencil the place where the knitting-needle stops for half an ounce. I see I was not mistaken in what would take your fancy. I will hang it up here. You shall make one for yourselves, and spend what time you please with it. You will not then easily forget how elastic the film is."

Now the surface tension of a soap film is so small that if the knitting-needle and pill box weighed nothing the slate frame chosen must have been eight or nine feet across, and the knitting-needle the same length, or if the letter and the pill box weighed nothing the knitting needle, if of steel, must have been a great deal finer than any in ordinary use. But even if the experiment were being performed on a minor planet, instead of at Manchester, where with diminished gravitation the half-ounce knitting-needle and pill box would only just be sufficient to balance the tension of the soap film, the description would give the false impression that like a metal or other spring the tension of the soap film increases as the film is stretched, and so is able to rest steadily at some point which depends on the stretching weight. One obviously invented experiment described with all the circumstance and detail that this is, is sufficient to shake one's faith in the genuineness of other demonstrations. C. V. B.

#### STRETTON ON THE LOCOMOTIVE

*The Locomotive Engine and its Development*. By Clement E. Stretton, C.E. (London: Crosby Lockwood and Son, 1892)

THE author of this work is well known to the railway world as one who has long taken a great interest in everything pertaining thereto. No one probably has a better knowledge of the history and development of the locomotive. It is with much pleasure we welcome the volume before us. The author very properly gives to Trevithick the name of "Father of the Locomotive," he having used high-pressure steam, the smooth rail, and the blast pipe, some years before either Hedley or Stephenson began to experiment. It is a pity so many men connected with the early progress of the locomotive should have been lost to fame, all did their share—the few only have been handed down to posterity. William James, for instance, certainly should not be forgotten, he having had a large share of the work in proving the locomotive to be a suitable machine for hauling trains, as against the system of fixed engines and rope haulage, and to him is largely due Stephenson's success on the Liverpool and Manchester Railway.

Richard Trevithick was born April 13, 1771, in the parish of Illogan in Cornwall. He was a mechanical genius in many ways. His first engine was made in the year 1803. This engine ran on four wheels, the boiler was arranged horizontally and had a wrought iron return fire-tube, the cylinder was 8½ inches in diameter, and the piston had a stroke of 4 feet 6 inches. It was arranged horizontally, the crosshead driving a shaft in front of the boiler by means of a return connecting-rod. This

shaft carried a heavy flywheel, and was connected to the carrying wheels of the engine by means of spur gearing. The exhaust steam was discharged into the chimney, ensuring an efficient supply of steam.

In the year 1808 Trevithick laid down a circular railway in a field which now forms the southern half of Euston Square. The locomotive exhibited had a vertical cylinder, the crosshead being coupled direct to the hind pair of wheels. This engine weighed about ten tons, and ran at an approximate speed of ten to twelve miles per hour. From these data it will be at once seen that Trevithick was before either Hedley or Stephenson with the invention of the locomotive engine, since both Hedley's and Stephenson's experiments date from the year 1813.

The volume under notice is full of historical data having reference to these early experiments. The author has taken great pains in arranging the matter. Further on in the book, chapter iii., another most interesting subject is dealt with. "The Battle of the Gauges" will long be remembered by engineers. The standard gauge of railways in this country is 4 feet 8½ inches, measured between the heads of the rails. This peculiar dimension appears to have been originally due to the tramways in use at the collieries where the original experiments were carried out by Stephenson and others, and was adopted for the railways when first projected and locomotives used. The great exception to this standard was the seven-foot gauge of the Great Western Railway. This railway, when projected by Mr. Brunel, was intended to eclipse the narrow-gauge of railways, both in speed and comfort when travelling. This competition, however, is claimed by the author as having been the means of hastening the growth and perfecting the locomotive. Looking at the question from the present day, the 4 feet 8½ inch, or standard gauge, is certainly too narrow, the power of the locomotive has gradually been increasing since Stephenson's day, and a point will soon be reached when radical changes must be made in locomotive design, in order to increase the power still more. On the other hand, the now obsolete seven-foot gauge of Brunel was too large. The Indian engineers have adopted the gauge of 5 feet 6 inches for the standard of that country. This dimension appears to be a "happy mean," and one with which locomotive engineers may revel in large journals and free steam and exhaust ports in locomotives fitted with inside cylinders.

It is amusing to read that American engines commenced their competition with the English engine in the year 1840, when some were imported to work the trains up the Lickey incline of one in thirty-seven on the Birmingham and Gloucester Railway. These engines were made by Messrs. Norris and Co., of Philadelphia, weighing slightly under eleven tons. The author tells us they thoroughly beat the English engine of that day doing this particular service.

Every locomotive engineer knows what the Stephenson link motion is—the apprentice in his first year generally prides himself on having mastered its details, yet, for all this, the author tells us to call this old friend by another name! It seems that this gear is really due to Mr. William Howe, an employé of Messrs. R. Stephenson

and Co., and was adopted by them and first fitted to an engine for the North Midland Railway in the year 1842. It may here be noted that the question of valve gear generally is not sufficiently described or illustrated in this volume. The index contains several references, but these are very superficial. This becomes all the more apparent when the Joy valve gear is fully described and illustrated, besides a diagram showing results of working.

The Joy valve gear is in the opinion of many an unsuitable gear for a locomotive. It must be evident that any gear which derives its valve motions principally from the vertical movements of the connecting-rod cannot give a good distribution of steam, for the reason that the vertical movements of the connecting rod are affected by those of the driving axle. The driving-axle is not always in the same position as regards the frames and cylinders owing to the undulations of the road, the oscillation of the engine, and the varying condition of the springs, a movement of half-an-inch above and below the normal position of the driving-axle is quite within the limits of actual practice. This movement is sufficient to affect the true movement of the valve, indeed, it is enough to destroy the lead either on the front or back ports as the case may be. Besides this objection, the Joy gear has nominally a uniform lead for all degrees of expansion, whereas it is usually considered necessary to increase the lead for higher grades of expansion and speed of engine. Some locomotive engineers are willing to risk this defective steam distribution in order to take advantage of the undoubted improvements in design the adoption of this valve gear allows. These mainly consist in the increase in length of the driving-axle bearings for engines with inside cylinders, there being no eccentrics to find room for between the crank webs. The cylinders can be consequently placed closer together, and the steam chest arranged either above or below the cylinders, as the case may be, without the use of rocking shafts or intermediate gear.

Chapter IV deals with modern locomotives for main line trains. Many well-known engines are illustrated and described, and we naturally find the Compound Locomotives of Messrs. Worsdell and Webb included in the number. The author evidently is not enamoured with the compound locomotive, saying that "facts" are in favour of the simple engine. It is here to be noted that no locomotive superintendent in this country, excepting the patentees of the respective systems, has adopted the compound system. What this is due to is uncertain, because the two-cylinder type of compound locomotive known as the Worsdell system has certainly given good results in India and other countries, comparing favourably with the simple engine. The "Gladstone" locomotive, designed by the late Mr. William Stroudley, is among those illustrated. This raises the interesting question as to the wisdom of using large leading coupled wheels for express work, many engineers prefer a bogie in front, deeming it safer. But when the London and South Western Railway practically copy Mr. Stroudley's arrangement of wheels in their latest engines for mixed traffic, one is apt to be surprised at the change coming from the "bogie" head quarters, and to surmise that anything will do. There is, however, nothing new in the adoption

of large leading coupled wheels, many engines were running in India of this design before Mr Stroudley adopted it, and the whole question can be narrowed down to the comparative life of tyres under different types of engines, there can be no doubt that a four-wheeled bogie or a Bissel truck in front saves the tyres of the leading coupled wheels, a larger mileage being obtained from them before they require to be returned.

Chapter V includes a description of the sand blast arrangement for sanding the rails to prevent the slipping of the driving wheels. This apparatus, small as it is, has left its mark on the design of express locomotives. The single engine has again come to the front for express work with marked success, the latest design of Midland and Caledonian engines being examples.

This volume taken as a whole is most interesting, and should be of value to all connected with the railway system of this country as a book of reference.

N J LOKYER

### OUR BOOK SHELF

*Sketches of British Insects*. By Rev W Houghton, MA, FLS, MSL (London: O. Newmann and Co., 1892).

It is satisfactory to find that there is sufficient demand for elementary books on entomology to render necessary a new edition of Mr Houghton's "Sketches of British Insects," and for those who, as dwellers in the country, wish to gain some insight into the insect life around them few better books could be found. The differences between the several orders of insects and the main distinctions of the families are plainly and intelligibly set forth, though in a few instances the definition of terms and sections is somewhat faulty, thus, "Arthropod" would be more fitly translated "with jointed feet" instead of "with feet at the joints," and the numerous exceptions are not enough insisted on, there being for instance many insects with aquatic respiration and crustacea with aerial. In Lepidoptera the tongue is often completely absent, whilst in butterflies the forelegs are never wanting, as stated, though in certain families they are rudimentary in both sexes or in the male only, and again the two pairs of spurs on the hind tibiae are present in the vast majority of moths and also in many skippers. The insects selected for description are well chosen, either as being conspicuous and typical of their families or as illustrating by their peculiarities some principle of adaptation to surroundings, though in many cases the classification is not according to modern ideas, thus, the clearwings (*Sesia*, &c.) have no affinities with the bee-hawks (*Hemaris*), which belong to the *Sphinx* and the snouts (*Hypena*) are *Noctues* not *Pyrals*. The account in the introduction of the structure and metamorphoses is especially simple and clear, and the small volume is on the whole an admirable sketch of British insect life, though the coloration of the plates might have been made much less crude without adding materially to the cost of production.

*The Birds of Lancashire*. By F S Mitchell. Second Edition. Revised and Annotated by Howard Saunders (London: Gurney and Jackson, 1892.)

WE are glad to welcome a new edition of this book, which we reviewed shortly after the publication of the first edition *NATURE*, vol xxxii p 241. The task of preparing a new edition (in the absence of Mr.

Mitchell from England) was undertaken by Mr. Howard Saunders, and it is scarcely necessary to say that he has discharged his duty thoroughly. He has no personal connection with Lancashire, but he has had much help from local authorities, especially from Mr R J Howard, of Blackburn, and with their aid he has brought the book, as far practicable, up to date. Several species have been added to the list, and there is a new index.

*Borneo: Its Geology and Mineral Resources*. By Theodor Posewitz. Translated from the German by Frederick H Hatch (London: Edward Stanford, 1892.)

THE original work, of which this is a translation, has been reviewed in *NATURE* (vol xl p 49), so that it is unnecessary now to do more than record the fact that an English rendering of the book has been published. Dr Hatch has done his work most conscientiously, and the translation is likely to be much appreciated by students of geology and mineralogy, and by all who have any reason for being specially interested in the material resources of Borneo.

### LETTERS TO THE EDITOR

(The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of *NATURE*. No notice is taken of anonymous communications.)

#### "A New Course of Chemical Instruction"

I AM much interested in the article in *NATURE* for September 29, entitled "A New Course of Chemical Instruction," especially as the writer, in the criticism of the book in question, whilst thinking that the method there advocated has theoretically more to recommend it than any other, doubts whether practically the time required is not an insurmountable obstacle.

For four years I have been able to teach beginners in Chemistry on a method very closely allied to the one here proposed, that is to say, one in which no experiment is performed without a definite object in view—the final object being the solution of a given problem and no idea being given to the pupil of what the result will be, and I am glad to be able to say that the time required is not such a serious drawback as might be supposed, whilst the intense interest aroused and the training in scientific methods of work amply compensate for the slower acquirement of chemical facts.

I have not the advantage of being acquainted with Mr Castell-Evans' book, so that I am not quite sure how nearly my work would agree with his course, but the fundamental principle is undoubtedly the same, and is the one laid down by Dr Armstrong in the report of the British Association Committee on Chemical Teaching, where he advocates the teaching of Chemical method rather than Chemical facts.

What generally appeals the beginner in Chemistry is the multitude of facts to be remembered, it seems a mere question of memory, and in consequence so dull and uninteresting, that the explosion or "burst up" is the one point to be looked forward to in the lesson. By this new method the pupils themselves are put into the position of discoverers, they know why they are at work, what it is they want to discover, and as one experiment after another adds a new link to the chain of evidence which is solving their problem, their interest grows so rapidly, that I have seen at a demonstration lesson a whole class rise to their feet with excitement when the final touch was being put to the problem which it had taken them three or four lessons to solve. Facts learned with so much interest are not forgotten and form a solid basis which it is true is slowly laid, especially at first, but it is interesting to see how much more quickly and easily later facts are assimilated, each one fitting itself in with the knowledge already acquired, and even when it becomes a ques-

tion of reading the account of work which it is impossible for the student to repeat for himself, the methods adopted are quickly understood and easily remembered, because the general methods of analysis and synthesis have, in an easy form, not only been used, but discovered by the student himself.

This method of course breaks down where an elaborate examination syllabus is imposed upon the beginner from the outset, and even where this is not the case, every teacher must adapt the method to his own conditions, only and always keeping the fundamental principle in view.

For the beginner in Chemistry whether he is later to specialise in this subject or not, experience has convinced me that the teaching of facts must give way to the teaching of method if a sound basis is to be laid in chemical science, whilst the subject opens the whole question of the value of Chemistry teaching from the educational point of view.

GRACE HEATH

### The Temperature of the Human Body

THERE is a problem partly physiological and partly physical which I shall be grateful if any reader of NATURE can throw light upon.

1 *The physiological*—I am assured by medical opinion in which I have confidence that the temperature of the human body is invariable from pole to equator of the earth. The question I want to ask, assuming this to be true, is this: What is the action in the body which exactly and everywhere counterbalances the radiation and conduction of heat in the one case from the body and in the other to the body? I thought at first that perspiration might have something to do with it, but my medical authority assures me that at the equator a man who perspires freely has exactly the same temperature as one that perspires little, although the former will be in good and the latter in bad health.

2 *The physical*—Treating the animal as a heat engine, one is apt to think of the source of heat as the animal heat engendered by the combustion going on in his frame, and the refrigerator as the surrounding air at lower temperature—in the experience of most of us. The animal then does work at the expense of this heat during its transfer from source to refrigerator, as in an ordinary engine. On the other hand, the animal in equatorial regions must, if the physiological statement above be a fact, be often the coldest of surrounding bodies. Does he also do work at the expense of the heat of combustion in his body, and if so is this vital action an exception to the second law of thermodynamics? If not, does he do work at the expense of the heat which is conducted into his body from hotter surrounding bodies, which heat, when he is doing no external work, still does not raise the temperature of his body?

### Comet II 1892 (Denning, March 18)

THIS comet is still a tolerably easy object in my 10 inch reflector and will doubtless continue to be visible during the greater part of the ensuing winter. It is now approaching the earth, and its brightness is increasing slightly. During the next two months it will traverse Orion.

I observed the comet on September 30, when it was in the same field as the 6th mag. star Piazzi VI 144 (Lalande, 12546). By differential observations with that star I found the place of the comet to be

GMT	a.		d.	
	h	m	h	m
1892, Sept 30	12	50	6 25	51
				+14 11

The theoretical brightness, as given in Schorr's ephemeris, was 0.62, but to my eye the comet seemed quite as plain as in March last. The nucleus was, perhaps, not so distinct, but the surrounding nebulosity appeared to be more extended than on previous occasions.

The comet will be close to  $\zeta$  Orionis (the southernmost star in the belt) about November 14, and passes very near  $\beta$  Orionis (Rigel) on November 30.

Bristol, October 2

W. F. DENNING

### Cirro-stratus

A RATHER perfect example of one variety of this cloud was seen here in the afternoon of September 27. A rapid fall of the

NO. 1197. VOL. 46]

barometer until 5 A.M., accompanied by a high wind, had been followed by a steady rise, the wind moderating some hours later. At 2 p.m., with a westerly light air, the sheet of cirro-stratus which overspread the sky appeared in the form of a series of very perfect undulations, stretching nearly north and south. These were about fourteen in number, crowded together towards the east. The lower surface of the sheet was sharply defined, and could be followed with ease in its successive rise and fall. The cloud filaments could be also traced, preserving their perpendicularity to the wave fronts and conforming to the undulations of the lower surface with a closeness which I had not before observed, although sheets of cirro-stratus are common here. The whole system was drifting slowly to the east.

Crawford Observatory, Queen's College, Cork

### A New Habitat for Cladonema

WILL you kindly allow me through your columns to note a habitat for this genus not given in Allman or Hincks. Several weeks ago I received some sponge from Mr. Sindt, of Jersey, and on examining it with a hand-lens detected four polypites of Cladonema, one, at least, of which is still alive.

HENRY SCHERREN

5 Osborne Road, Sloud Green, N

### TO DRAW A MERCATOR CHART ON ONE SHEET REPRESENTING THE WHOLE OF ANY COMPLEXLY CONTINUOUS CLOSED SURFACE.

IF a solid is not pierced by any perforation, its surface is called simply continuous, however complicated its shape may be. If a solid has one or more perforations, or tunnels, its whole bounding surface is called "complexly continuous", duplely when there is only one perforation, ( $n+1$ )-plexly when there are  $n$  perforations. The whole surface of a group of  $n$  anchor-rings (or "toroids") cemented together in any relative positions is a convenient and easily understood type of an ( $n+1$ )-plexly continuous closed surface.

Let the diagram represent a quadruplexly continuous closed surface made of very thin sheet metal, uniform as to thickness and homogeneous as to quality throughout. To prepare for making a Mercator chart of it, cut it open between perforations C and B, B and A, A and outer space, in the manner indicated at  $\frac{2}{3}$ ,  $\frac{1}{4}$ , and  $\pm$ . Apply infinitely conductive borders to the two lips separated by the cut at  $\pm$ , and apply the electrodes of a voltaic

battery to these borders. By aid of movable electrodes of a voltmeter trace, on the metallic surface, and a very large number ( $n-1$ , of equidifferent equipotential closed curves between the + and - borders. Divide any one of these equipotentials<sup>2</sup> into parts each equal to the

<sup>1</sup> A "hole" may mean a deep hollow, not through with two open ends. The word "tunnel" is inappropriate for the aperture of an anchor ring. Neither "hole" nor "tunnel" being unacceptably available, I am compelled to use the longer word "perforation".

<sup>2</sup> Two sentences of my previous article ("Generalisation of Mercator's Projection") in § 3, and in last paragraph but one, are manifestly wrong, and must be corrected to agree with the rule given for dividing into infinitesimal squares, in the present text.

infinitesimal distance perpendicularly across it to the next equipotential on either side of it, and through the divisional points draw curves, cutting the equipotentials at right angles. These curves are the stream lines. They and the  $(n+1)$  closed equipotentials (including the infinitely conductive borders) divide the whole surface into  $n \times m$  infinitesimal squares, if  $m$  be the number of divisions which we found in the equipotential. The arrows on the diagram show the general direction of the electric current in different parts of the complex circuit, each arrow representing it for the thin metal shell on either far or near side of the ideal section by the paper.

Considering carefully the stream-lines in the neighbourhoods of the four open lips marked in order of the stream 1, 2, 3, 4, we see that for each of these lips there is one stream-line which strikes it perpendicularly on one side and leaves it perpendicularly on the other, and which I call the flux-shed-line (or, for brevity, the flux-shed) for the lip to which it belongs. The stream lines infinitely near to the flux-shed, on its two sides, pass infinitely close round the two sides of the lip, and come in infinitely near to the continuation of the flux-shed on its two sides. Let  $F_1, F_2, F_3, F_4$  (not shown on the diagram) be the points on the  $+$  terminal lip from which the flux-sheds of the lips 1, 2, 3, 4 proceed, and let  $G_1, G_2, G_3, G_4$  be the points at which they fall on the  $-$  lip. Let  $S_1, T_1, S_2, T_2$ , &c., denote the points on the four lips at which they are struck and left by their flux shed lines.

Let  $\phi_1, \phi_2, \phi_3, \phi_4, \phi_5, \phi_6, \phi_7, \phi_8, \phi_9$  be the differences of potential from the  $+$  lip to  $S_1$ , from  $S_1$  to  $T_1, T_1$  to  $S_2, S_2$  to  $T_2$ , and  $T_2$  to the  $-$  lip. Measure these nine differences of potential. We are now ready to make the Mercator chart. We might indeed have done so without these elaborate considerations and measurements, simply by following the rule of my previous article, but the chart so obtained would have infinite contraction at eight points, the points corresponding to  $S_1, T_1, S_2, T_2$ . This fault is avoided, and a finite chart showing the whole surface on a finite scale in every part is obtained by the following process.

Take a long cylindric tube of thin sheet metal, of the same thickness and conductivity as that of our original surface, and on any circle  $H$  round it, mark four points,  $h_1, h_2, h_3, h_4$ , at consecutive distances along its circumference proportional respectively to the numbers of the  $m$  stream-lines which we find between  $F_1$  and  $F_2, F_2$  and  $F_3, F_3$  and  $F_4, F_4$  and  $F_1$  on the  $+$  lip of our original surface. Through  $h_1, h_2, h_3, h_4$  draw lines parallel to the axis of the cylinder.

Let now an electric current equal to the total current which we had from the  $+$  lip to the  $-$  lip through the original surface be maintained through our present cylinder by a voltaic battery with electrodes applied to places on the cylinder very far distant on the two sides of the circle  $H$ . Mark on the cylinder eight circles,  $K_1, K_2, K_3, K_4$ , at distances consecutively proportional to  $\phi_1, \phi_2, \phi_3, \phi_4, \phi_5, \phi_6, \phi_7, \phi_8$ , and absolutely such that  $\phi_1, \phi_2, \phi_3, \phi_4$  are equal to the differences of their potentials from one another in order.

Bore four small holes in the metal between the circles  $K_1$  and  $K_2, K_2$  and  $K_3, K_3$  and  $K_4, K_4$  and  $K_1$  on the parallel straight lines through  $h_1, h_2, h_3, h_4$ , respectively. Enlarge these holes and alter their positions, so that the altered stream-lines through  $h_1, h_2, h_3, h_4$  (these points supposed fixed and very distant) shall still be their flux-sheds. While always maintaining this condition, enlarge the holes and alter their positions until the extreme differences of potential in their lips become  $\phi_1, \phi_2, \phi_3, \phi_4$ , and the differences of potential between the lips in succession become  $\phi_2, \phi_3, \phi_4$ . In thus continuously changing the holes we might change their shapes arbitrarily, but to fix our ideas, we may suppose them to be always made circular. This makes the problem determinate, except the distance from the circle  $H$  of the hole nearest to it,

which may be anything we pleased, provided it is very large in proportion to the diameter of the cylinder.

The determinate problem thus proposed is clearly possible, and the solution is clearly unique. It is of a highly transcendental character, viewed as a problem for mathematical analysis, but an obvious method of "trial and error" gives its solution by electric measurement, with quite a moderate amount of labour if moderate accuracy suffices.

When the holes have been finally adjusted to fulfil our conditions, draw by aid of the voltmeter and movable electrodes, the equipotentials, for  $\phi_1$  above the greatest potential of lip 1, and for  $\phi_2$  below the least potential of lip 4, and between these equipotentials, which we shall call  $f$  and  $g$ , draw  $n-1$  equidifferent equipotentials. Draw the stream-lines, making infinitesimal squares with these according to the rule given above in the present article. It will be found that the number of the stream-lines is  $m$ , the same as on our original surface, and the whole number of infinitesimal squares on the cylinder between  $f$  and  $g$  is  $m \times n$ . Cut the cylinder through at  $f$  and  $g$ , cut it open by any stream-line from  $f$  to  $g$ , and open it out flat. We thus have a Mercator chart bounded by four curves cutting one another at right angles, and divided into  $m \times n$  infinitesimal squares, corresponding individually to the  $m \times n$  squares into which we divided the original surface by our first electric process. In this chart there are four circular blanks corresponding to the lips 1, 2, 3, 4 of our diagram, and there is exact correspondence of their flux-sheds and neighbouring stream lines, and of the disturbances, which they produce in the equipotentials, with the analogous features at the lips of the original surface as cut for our process. The solution of this geometrical problem was a necessity for the dynamical problem with which I have been occupied, and this is my excuse for working it out, though it might be considered as devoid of interest in itself.

KELVIN.

#### THE RECENT ERUPTION OF ETNA<sup>1</sup>

THE southern flank of Etna has been the site of three consecutive eruptions, remarkable for the diversity of the phenomena they presented.

On March 22, 1883, after several violent shocks of earthquake, the ground was rent open in a NE and SW direction, almost on the continuation of the big rift formed in the eruption of 1879, and near Monte Concilio a most interesting eruptive apparatus was formed. Very quickly, however, the eruption was arrested, but the eruptive energy had not had sufficient vent, as evidence of which were the frequent shocks which followed it and persisted, until on March 18, 1886, the ground was again split open as a prolongation of the rift of 1883, giving rise to an imposing eruption, during which an enormous quantity of lava was poured forth. This eruption from the very beginning manifested a great explosive force. The fragmentary materials were projected to an extraordinary height from several craterets formed along the rift, most of which, however, soon became quiet and were buried by the ejectamenta of the others, remaining alone the one twin crater now called Monte Gemmellaro. After this eruption the geodynamic phenomena and the volcanic activity at the central crater remained exceedingly feeble up to the last few days, so that this actual eruption did not present any grand display of premonitory phenomena.

On the evening of July 8, at about 10.30, the central crater of Etna began to send up a dense column of vapour, charged with dust, lapilli, and large rock fragments, which rose as an imposing mass with the

<sup>1</sup> This paper was written in Italian, and sent as a letter to Dr. H. J. Johnston Davis, who has kindly translated it for NATURE, as requested by the author.

characteristic pine-shape of explosive eruptions, and illuminated by lightnings

After half an hour this phenomenon ceased, and the smoke-plume was swept away by the higher currents of the atmosphere. I was able to ascertain in my excursion to the summit of Etna, in company with Mr. Rudler, curator of the Museum of Practical Geology of London, that the central crater was much modified by the short eruption. It presented two mouths, separated by a partition, whilst its upper edge was much broken down, so that it was enlarged. The ejected materials were composed of fragments of very much altered lavas that fell chiefly to the westward. During the night the ground was in a state of tremor, and at 2.45 a.m. of the 9th, a strong shock of earthquake was felt all over the Etnaean region, producing slight damage to the walls of buildings.

Towards 1.20 p.m., without any further shock sensible in the inhabited regions, the southern flank of Etna was

which is to the south of the new craters it divided in two principal branches and precipitated itself on the plain from which rises Monte Gemmellaro, forming three cascades of living fire. It here spread out, and the two branches, directing their course to the south, threatened Nicolosi, Belpasso, and Pedara. The more eastern ramification, when it reached the neighbourhood of Monte Albano, began to slow down and was already on the 12th advancing about two metres per hour, but increasing the breadth of its front and its thickness. On the other hand the western branch, which was invading the cultivated land, advanced in the steeper ground over fifty metres the hour, as I observed in my first visit on July 11. This stream was of a bright red colour, slightly covered by scoria. Near Monte Concilio it had filled up a valley, assuming a thickness of over 40 m. From Monte Ardicazzi we had presented to our view an immense expanse of fire from which rose crests and hills all in

FIG. 1.—Taken by Sig. Ledru on July 17. (No. 1, 2) are craters No. 1 and 2. (No. 3 and 4) craters No. 3 and 4 in process of formation. —(a) Crateriform vent at the north base of crater No. 1. —(b) Monte Nero about one km. west of the craters.

rent open, and I could observe from Acireale a dense curtain of smoke rush up in great vortices, accompanied by continual rumblings. Towards evening one could see that the lava had advanced very rapidly in a southern direction. At the upper part it was observable that several jets, arranged in a linear manner, of fragmentary materials were being shot up to a great height, especially at three main points on the new and great rift. The explosive force of this eruption was much less than that of the eruption of 1886, in which the fragmentary ejecta were shot up to a height of 1200 metres, whilst in the present case the height rarely exceeded 500 metres. This fact depends on the great altitude and the great size of the new fissure, which afforded a free escape for the energy of the volcano, and gave forth a much greater quantity of lava. The lava in less than three days travelled more than four kilometres, and having surrounded Monte Nero,

candescant, divided by deep depressions. It appeared like the sea in a tempest, the waves of which in their fury were suddenly petrified. From the crests were constantly being detached fresh incandescent masses which rolled down and choked the depressions, whilst new gushes raised the masses of scoria into new hills of fire. Amidst the phonolitic noise of the lava in movement, I noticed gigantic puffings produced by the escape of the vapour of  $H_2O$ , which, accumulating amidst the mass of the lava, formed gigantic bubbles which rose and burst, allowing the escape of the compressed gas.

The eruption was very active during the following days with short intervals of diminution or marked increase. Remarkable phenomena were the blasts which shook the doors and windows at Nicolosi, Acireale, and Catania, and, at localities nearer the point of eruption, even the walls

On July 16 I started again, with my brother Giovanni, to approach the site of eruption. From Monte Caprioletto, which is about 1200 m distant, we could observe not only the three principal craters above mentioned, but also two others lower down, which so far had not grown to any important size.

Approaching still farther, we stopped at about 300 m off on the west, on a plain upon which grows the *Astragalus Siculus*, the bushes of which are now covered by large lapilli, and in part are burnt. The crater, which for brevity we will call No. 1, gave forth large and continual bursts of dust and scoria from its summit, and also from other points on its northern wall at the base of which issued a jet of light-grey vapour, which came from a little imbutiform crater separated from the main one by a partition of small size, from this were ejected a little dust and occasionally stones. The explosions of No. 1 were not accompanied by loud noises (*boats, hellowings*), but

Also in this last crater the explosions took place from several points of its funnel-shaped cavity, and we saw, at about mid-day of the 17th, much of its southern side destroyed by several bursts that took place from that point.

Both of these craters, already of considerable height, had an elliptical base, and specially No. 1, the maximum diameter of which is in the direction of the great rift, along which they are distributed.

The third crater, which we will call No. 3, adjoining the preceding one, presents a large depression to the south. It gave forth frequent bursts of incandescent lava fragments, with a constant noise resembling the constant discharge of much musketry, and accompanied by yellowish-white vapours. The emission of dust was rare, and only occurred when the eruptive bursts scored the north side of the crater. The fragments of incandescent lava, which in this crater were not accompanied by a trail of dust, often

FIG. 2. — By Sig. Ledru on August 19, at 100 m to the north-east of the craters. (5) Crater of August 11. (4) Crater to the west which was in activity only on July 9. (1) Crater No. 1.

by strong and continual roarings like the sea in a tempest. Crater No. 2, more regular in form, gave forth frequent eruptions of dust, with many incandescent projectiles. In the moments of calm between one explosion and another, a slight white vapour escaped. The first burst of the explosion might be compared to a gigantic pointed jet preceded by black dust and sand, which rose with great rapidity in consequence of the great ascensional velocity, which was gradually impeded by the resistance of the air, then the column of black smoke charged with dust began to open out the immense vortices of compressed vapour which, always rising, assumed an imposing and characteristic aspect. The pieces of scoria were followed by a trail of dust both in their rise and fall, and when they struck the flanks of the mountain as they rolled down, they raised a cloud of dust and gave forth a characteristic sound. When they were numerous the mountain became all covered by a yellow dust.

NO. 197, VOL. 46]

were torn asunder in the air, being reduced to fragments.

The discharge of smoke from this crater occurred from the highest part, then there was the point at which occurred the numerous explosions of lava, then another jet of smoke, in its turn followed by another point lower down, from which occurred the explosions of the incandescent projectiles that gradually formed a crater, which we will distinguish as No. 4.

In general, while we were moving about to the westward of the craters on the morning of the 17th, the eruption was exhibiting comparatively little energy. Gradually, however, the explosions increased in violence, and the ejecta became more numerous. It is worthy of notice that the smoke, according to the place whence it issued was white, blue, light or dark grey, black, yellow, and even iridescent. Approaching nearer the craters, we attempted to encircle them on the north, when we found numerous

little fissures in the ground in a direction approximately parallel to that of the main rift. These, often over a metre in breadth, are choked by the loose materials forming the surface, and in part obstructed by the loose materials forming their sides. Higher up we found a wide cleft, which, starting from a higher point, was prolonged downwards towards the craters and was lost beneath the lava. Upon this fissure were arranged a series of crateriform elevations, some of which were extinct, and others still presenting a little solfataric action. On July 9, at the commencement of the eruption, lava and fragmentary ejecta also issued by this cleft, but it seems, the same day, to have become obstructed, and the tongue of lava which menaced the Casa del Bosco stopped, and the eruptive phenomena were diverted to the other more eastern fissure.

It is absolutely impossible to accept the statement that this cleft represents the fire vents of the eruption of 1766,

re-ejected, or are pieces of rock detached from the walls of the volcanic chimney. Certainly from the last source are derived quartzites, which we collected amongst the ejected materials from this crater. This quartzite is semi-vitreous, very similar to that which we collected from the craters of the eruptions of 1883 and 1886. These facts evidently showed that all these three eruptions have traversed similar strata and that all have arisen over the same principal cleft. In fact the new eruptive apparatus formed at the base of the Montagnola about 1900 m above sea level, lies on the northern prolongation of the rift of 1886, in a plain gently inclined toward the south, and which towards the east presents a marked slope, so that the new craters are much higher on their eastern side. In the great paroxysmal eruptions, and when a large rift opens at the surface of the earth, it is generally the rule that the eruptive mouth from which the lava flows without much explosive force is situated

FIG. 3.—Taken by Sig. Modon on July 13, 1892, at 150 m. to the north west of the craters. Craters No. 1 and 2. (m) Monte Nero. (n) Little northern crater.

and that the solfataric phenomena which the cleft now exhibits are only due to the near vicinity of the new volcanic outlet, for—putting aside the fact that in visits anterior to the present eruption I had never found any sign of such, and this is confirmed by people accustomed to the locality—it is easy also to be convinced from the nature of the materials composing these craterets. These materials are so new as to leave no doubt as to their origin, and consist, those higher up, specially of blocks of old lava torn from the sides of the cleft, lower down they are principally scoria and other loose materials of recent formation.

Approaching still nearer, we were able to distinguish clearly that amongst the ejected materials of No. 1, besides the number of fragments of molten lava, there are often blocks of a dark grey colour that were already consolidated before their final ejection, which are either projectiles that have fallen back in the crater and have been

at its lowest extremity. The higher one goes along the fissure the less is the amount of lava that issues, but the greater is the explosive action, which higher still itself in turn diminishes. In the present eruption we have good examples of this. In fact, the small northern crater gave forth only dust, and very few fragments of new lava, and with little energy. No. 1 crater emitted much dust and also much lava, No. 2 more lava than dust, and Nos. 3 and 4 exclusively lava. The materials of the little northern crater (Fig. 3) are for the most part fragments of ancient lava, which lose their predominance in crater No. 1, and gradually disappear as one descends lower and lower. At the same time, as the old lava has a light bluish-grey colour and the fragments of the newer lava are much darker, the different craters exhibit different colours. This difference also depends in part upon the degree of fineness of the materials that compose the craters. In fact the northernmost crater at the beginning

of the rift had not sufficient power to eject large materials, but lifted them up and kept them in continual movement, reducing them to fine dust, which was easily carried out by the vapour. No 3, on the contrary, continually ejected large lumps of lava, often shooting them a considerable distance, whilst Nos 1 and 2 exhibited intermediate stages, quite confirming what has been said above.

Whilst we were there the eruption increased little by little. The ground commenced to vibrate, and at 3.47 p.m. we

FIG. 4.—Taken by Sig. Morin on July 18, 1892, at 300 m. to the north west of the craters. (1 and 2) craters No. 1 and 2. (a) Monte Nero. (d) Craters to the west which were in activity only on July 19.

felt a strong earthquake shock, followed by other frequent oscillations of the ground of less intensity but often very perceptible. In this new period of great activity general to all the craters the phenomena exhibited by No. 2 were worthy of remark. It no longer ejected dust, but pieces of hot lava with stronger explosions, which were more frequent but of shorter duration. Between one explosion and another there was slow evolution of white vapour, similar to that which rises from the fire-mouths and

FIG. 5.—Taken by Prof. Riccio on July 20, west of the craters. (1, 2, 3) craters No. 1, 2, and 3.

surface of the running lava. This floated above the crater, slightly disturbed by the wind, and when an explosion occurred it assumed a curious vibratory movement, rising a little, and then rapidly descending, then immediately was seen the first jet of solid materials, which, in its vertiginous upward course by vortex movement, sucked in the air over the crater edge, and the white vapours were drawn down, so looking as if they were being reabsorbed. This phenomenon, which attracted

our attention when I was with you on Stromboli and the members of the Geologists' Association,<sup>1</sup> would show that within crater No. 2 there is pasty lava, which is pushed up by the vapour in it, then the magma swells up, bursts, and the lava falls.

In this parasitic crater of Etna, however, the phenomena were on a much larger scale, as also were the smoke vortex rings which we looked down upon when we were together at Stromboli. Likewise the explosions were far louder, reverberating as a low-pitched roar by the echo of

FIG. 6.—Taken by Prof. Riccio on July 20, to the north west of the crater No. 1, 2, and 3. (a) Monte Nero.

the valleys, and they were audible in all the Etnean region, at Catania, Acireale, Giarre, and farther still for some dozens of kilometres from the craters. The air-shocks that accompanied these reports were very interesting. They represented a large undulation of the air, spreading with great velocity, reaching great distances, and contemporaneous with the audible vibrations.<sup>2</sup> While there we felt the blow on our bodies, and especially our chests and in the ears, at the Casa del Bosco we detected the shock against the walls, which trembled, and

FIG. 7.—Taken by G. Platania from the north north-east of the craters, July 30, 1891. (1) Crater No. 1. (c) Craters which were in activity only on July 9. The craters No. 2, 3, and 4 are hidden behind crater No. 1.

farther off at Catania and Acireale we heard the rattling of the windows and doors, which, strongly shaken,

<sup>1</sup> G. Platania "Stromboli e Vulcano, nel Settembre del 1889. Riposo 1889." This phenomenon I have often observed at Vesuvius, and I quite agree with Signor Platania as to its cause, as I have been able to look in the crater and watch the whole process.—Johnston-Lavis.

<sup>2</sup> The lava in this case is very like the boiling up of a viscous liquid in a long test-tube.—Johnston-Lavis.

<sup>3</sup> I have some doubts about the two mechanical disturbances travelling exactly at the same rate. When blasts are fired in a long tunnel the air-stroke is felt before the sound.—Johnston-Lavis.

give the impression of an earthquake, so that several times the people of these towns have rushed out into the streets. On July 14 I observed in Acireale that the large undulations of the air-blows which were propagated beyond 333 m per second, like sonorous vibrations, often arrived unaccompanied by noise, and strongly shook doors and windows.

These reports, these air-blows, and the abundant ejection of incandescent lava still further prove that in No. 2 crater there was pasty lava which swelled and burst, as we deduced from its effect on the white vapours.

This period of great activity, in which the thick shower of lava fragments projected from the different craters to great heights and spread over an area of 500m radius, reached its maximum about midnight, and then gently declined a little. In the same manner the eruption continued during the following days with great energy, but with a very gradual diminution in its intensity, interrupted more or less by strong spasms. The lava continued to advance, but diminished in velocity, while it extended in breadth and depth. The eastern branch very soon stopped, and also the western one, after having continued its destruction of very fertile ground. This having crossed the road known as the St. Leo, finally

Monte  
Neru Crater No. 4 Crater No. 3 Crater No. 2 Crater No. 1

stopped, whilst the new lava that continues to issue forms new ramifications and flows, which pass quite close to the earlier ones, and now actually are in contact with them, increasing the area covered. In the first paroxysm of the eruption the lava issued in great gushes all along the rift. Soon at the upper part commenced the dejection cones, and lower down the fire vents, and the lava flowed in abundance, and with explosions also in points where now are the craters, as, for example, Nos. 3 and 4. Later, when the explosive force had diminished, the lava issued without explosions, almost silently from different vents at the south end of the fissure on which are aligned the craters. These vents, therefore, have during the eruption varied in number and form. Some have assumed the function of dejection craters as occurred in Nos. 3 and 4, which gave passage to much lava as a current. Others have ceased to eject scoria, to send forth only torrents of lava, as, for example, the little mouth to the east of No. 4, the scoria rim of which exists only to the north, of about 20m high, whilst the south rim has been swept away by the current. Some of the mouths have been refilled by the lava flows, and whilst some have become extinct new ones have been formed.

In the last week of July, crater No. 2 assumed, for

some days, a new phase. Its explosions had become rare, long, and very grand, and the large mass of vapour, mixed with dust, brought back to my mind the eruption of Vulcano when we stood on the crater edge and watched and photographed the whole process, and stood our ground amidst showers of bombs and other projectiles (1888-90).<sup>1</sup> By this it lost the beautiful regular truncated cone form that it had at the beginning, and became irregular and broken-down towards the north, like No. 1.

At the commencement of August the eruption already seemed much diminished, craters No. 1 and 2 had ceased to eject stones little by little, gradually becoming blocked, and the enclosed lava was slowly cooling. In fact, on the recommencement of a period of renewed energy, the explosive force could no longer find an escape by them, so that on August 1 a new crater opened in a point higher up where the cleft to the west, which had only acted at the commencement of the eruption, joined another great rift on which the craters were formed. Then on August 9 occurred another violent eruptive spasm, which could not clear away the material that obstructed the craters, but opened a new way, always on the main cleft, between Nos. 1 and 2, and exactly at the north base of the last of these craters. Here a little funnel-shaped depression was formed which for a short time ejected enormous masses. This new crater, however, soon passed into the solfataric stage as Nos. 1, 2, and 3, and there remained in an energetic state of activity only the crater of August 11 and No. 4. That one which on August 21 measured in diameter only about 50 m, and had a height of about 60 m, later became elongated towards the S S W, and its grand and beautiful explosions, which I watched quite closely, in company with Mr. Rudler, on August 29, 30, and 31, were specially localized on the southern edge, so that they tended all the more to give it an elongated form on that more western cleft that was only in activity the first days of the eruption. No. 4, meanwhile, which I approached, ascending upon No. 3, gave forth frequent eruptions of hot lava cakes at regular intervals (about fifty per minute), accompanied by globes of yellowish vapour, and a noise similar to that which accompanies the globes of vapour from the locomotive when it commences to move.

By unanimous consent of all the studious inhabitants of Etna, the new craters have been called the Monti Silvestri, in honour of that well-known vulcanologist, the lamented Prof. Orazio Silvestri, who studied our volcano with so much fervour, registered so assiduously every slight disturbance, and described its paroxysms so well and with such originality, that his loss has been deeply felt by all men of science. September 7

## NOTES

THE Harveian oration will be delivered by Dr. J. H. Bridges at the Royal College of Physicians on Tuesday, October 18, at four o'clock.

THE Medical Session in London was opened on Monday, and introductory addresses were delivered in some of the schools attached to hospitals. A particularly interesting and suggestive address was delivered at the Westminster Hospital by Dr. Mercier, who dealt with various aspects of the problems connected with crime, pauperism, and insanity. Sir John Lubbock addressed the students at St. Thomas's Hospital.

ON Friday last Sir George Murray Humphry, F.R.S., delivered an interesting address at the opening of the first session.

<sup>1</sup> "South Italian Volcanoes," by Johnston Lavie, Naples, 1891. <sup>2</sup> "I Progetti Squarcati di Vulcano," by G. Platania. (Roma 1891.)

of the Queen's Faculty of Medicine in connection with Mason College, Birmingham. The union of the two institutions is likely to be of great service both to medicine and to pure science in the Midlands.

A MARINE biological station has been established at Bergen, in Norway, the funds having been raised by private donations and by subscriptions from learned societies. It will be under the control of Dr J. Brunchorst, and will supply ten places for Norwegian and foreign workers.

We regret to learn that M. Henri Douliot, who had been commissioned by the French government with a botanical expedition to the western coast of Madagascar, has died there of fever.

DR B. L. ROBINSON has been appointed Curator of the Herbarium of Harvard University, Cambridge, U.S.A., in succession to the late Prof. Sereno Watson.

MR WALTER L. COLLINGS, late Assistant Demonstrator in Zoology in St. Andrew's University, has been appointed to the vacant Demonstratorship in Zoology and Comparative Anatomy and Botany in Mason College, Birmingham.

A CIRCULAR appeal, dated September, 1892, and signed by Mr E. C. Pickering, Director of the Observatory of Harvard College, has been issued, inviting the wealthy to consider the opportunity offered for a donor of 200,000 dollars "to have his name permanently attached to a refracting telescope, which, besides being the largest in the world, would be more favourably situated than almost any other, and would have a field of work comparatively new." The telescope in question would be placed in the station established by Harvard College Observatory, near Arequipa in Peru, at an altitude of more than eight thousand feet. "During a large part of the year," says Mr Pickering, "the sky of Arequipa is nearly cloudless. A telescope station having an aperture of thirteen inches has been erected there, and has shown a remarkable degree of steadiness in the atmosphere. Night after night atmospheric conditions prevail which occur only at rare intervals, if ever, in Cambridge. Several of the diffraction rings surrounding the brighter stars are visible, close doubles in which the components are much less than a second apart are readily separated, and powers can be constantly employed which are so high as to be almost useless in Cambridge. In many researches the gain is as great as if the aperture of the instrument was doubled. Another important advantage of this station is that, as it is sixteen degrees south of the equator, the southern stars are all visible." The circular continues: "The planet Mars, when nearest the earth, is always far south. The study of the surface of this and of the other planets is greatly impeded by the unsteadiness of the air at most of the existing observatories. Even under the most favourable circumstances startling discoveries—relating, for example, to the existence of inhabitants in the planets—are not to be expected. Still, it is believed that in no other way are we so likely to add to our knowledge of planetary detail as by the plan here proposed." We venture to hope that the wealthy donor for whom Harvard is looking will soon be found.

BARON LEON DE LENOIR, of Nice, offers a prize of 3,000 francs to the inventor of the best application of the principles of the microphone in the construction of a portable apparatus for the improvement of hearing in deaf persons. Instruments for competition should be sent to Prof. Adam Politzer, or Prof. Victor von Lang, Vienna, before December 31, 1892. The prize will be awarded at the Fifth International Otological Congress at Florence in September, 1893. If no instrument is judged worthy of the prize, the jury reserve the right of announcing another competition, unless Baron Lenoir decides

to dispose of the prize otherwise. The following are the members of the jury—Prof. Adam Politzer (President), and Prof. Victor von Lang, Vienna; Dr. Bennis, Warsaw; Dr. Gellé, Paris; Prof. Urban Pritchard, London; Prof. St. John Roosa, New York; Prof. Grazi, Florence.

THE weather during the past week has been much disturbed by several depressions, which have caused heavy rainfalls over the whole of the kingdom, with hail and thunderstorms in many places. On the morning of September 30 the amount of rain measured on the south coast was an inch and a half, or about half the average for the month, and on the west coast, especially at Liverpool, much damage has been done by floods, occasioned by the excessive amount of rain. Temperature has been low for the season, the daily maxima rarely exceeding 60° in any part of the country, while in the north and west the readings have been much lower, frost has been recorded in the shade in the east of London, and the nights have been very cold generally. For several days a cyclonic area was situated over the United Kingdom, and strong winds were experienced on some coasts, a temporary improvement, however, occurred on Tuesday, although conditions remained very unstable. The *Weekly Weather Report* of the 1st inst. shows that the rainfall was in excess everywhere. In the south west of England it amounted to 1.2 inch, but there was still a deficiency of 7.5 inches since the beginning of the year. The temperature was below its mean value in all districts except the south of England and the Channel Islands, the deficiency being greatest in Scotland and Ireland.

SOME results of seven years' meteorological observations on the Pic du Midi, at a height of about 9500 feet, have been recently published by M. Klengel. The annual mean temperature is  $-2.2^{\circ}\text{C}$ . The annual variation,  $14.3$ , is only one degree less than at Tarbes on the plain, and is about that of the Sonnblick (which is some 800 feet higher than the Pic). April is abnormally cold ( $-6.2$ ), and this is attributed to the fact that the Pic stands in Van Bebber's fifth depression-pa'h, which is most frequented in that month. While Pic du Midi represents the extreme continental type of high mountain climates, and Etna the oceanic type, in nearly the same latitude, the Sonnblick and the Pic du Midi represent transition types. The maximum zone of precipitation on the Pic lies at about 7700 to 8000 feet, above this there is marked diminution. The results in general show that even at a height of nearly two miles the distribution of land and water on the earth's surface has a considerable influence on climate.

A SHOCK of earthquake, lasting from three to five seconds, was felt at Huelva, between twelve and one o'clock on the morning of September 29. According to a Reuter telegram, three shocks were noticed, the first being weaker than the succeeding disturbances. The direction of the seismic wave was taken from north to south, and the subterranean rumblings were heard very distinctly over a large area. The inhabitants were greatly terrified, but nobody was injured. Many windows were smashed, but beyond this the damage was insignificant.

A CURIOUS instance of globular lightning is referred to in the *Meteorologische Zeitschrift* for September 1892. On August 7, during a thunderstorm at Altenmarkt, near Fürstenseefeld, while the priest was administering the sacrament, the church was struck by lightning, followed by a loud explosion. A panic immediately ensued, and the congregation rushed out, notwithstanding the assurances of the priest that there was no danger. There was nothing to show how the lightning entered the church, but it is supposed it was by the conductor leading from the steeple. It is said to have been a large globe, tapering towards the upper part, and after the explosion it left a strong sulphurous smell. The explosion was very loud and shook the building.

THE last number of the *Berichte der Deutschen Botanischen Gesellschaft* contains an interim report on the progress of the negotiations concerning the nomenclature of genera, started by a committee of botanists at Berlin to supplement the decisions of the International Botanical Congress held at Paris in 1867. The proposals submitted last April to the consideration of 329 German and Austrian and 377 foreign botanists were the following:—(1) The year 1752 to be taken as the initial date for priority in names of genera, and 1753 for the names of species. (2) *Nomina nuda* and *semi nuda* to be rejected. Drawings and dried specimens without diagnoses to establish no claim to priority of a genus. (3) Similarly sounding generic names to be retained, even if differing only in the ending or by a single letter. (4) The names of the subsequent great or well-known genera to be preserved, even if they ought to be rejected by the strict rules of priority, especially in cases where no change in the names used up to the present can be proved. 360 replies had been received up to the time of the report, amongst them being 157 from Germany, 63 from Austria, and 19 from Great Britain and Ireland. The great majority expressed approval, at least, of the first three proposals. The botanical authorities of the British Museum favour the suggestions, those at Kew are against them.

M. G. TROUVÉ has built a luminous fountain for Mme. Patti, at her residence at Craig-y-Nos, an account of which appears in No. 11 of the *Comptes rendus*. The weight of this fountain is about 10,000 kgr., and the basin measures 6 m. in diameter. The illuminating power is represented by four incandescent lamps of 110 volts, each consuming 6 amperes. Thus the total electric energy amounts to 2640 watts, this gives, at three watts per candle, a light intensity of over 800 candles. The lamps are centred at the focus of four parabolic reflectors grouped under the glass chambers whence the water springs. As in the chamber fountains, the metallic adjuncts, which would have cast shadows, are eliminated. The water which falls from the upper to the lower basin is utilised to drive a small bucket-wheel, which governs the rotation of two superposed discs, concentric or otherwise, made of coloured glasses, which turn in the same or in the opposite sense, with equal or unequal velocities as required, between the reflectors and the glass. This combination of two discs with opposite rotations renders possible a variation in the play of colours of the liquid sheaves, which succeed each other with the unexpectedness of the kaleidoscope. The motive power can be chosen at pleasure. It may be hydraulic, electric, or by clockwork, of forms and dimensions in keeping with the character of the decoration. These fountains need neither expenses of installation nor costs of maintenance, and their price depends solely upon their artistic perfection and their importance. Hitherto the construction of luminous fountains has only been hindered by the impossibility of sufficiently illuminating the jets. To-day the problem is reversed. Since the light can be projected without sensible loss to great heights, the only difficulty will be to give a sufficiently high pressure to the water.

THE Manchester Field Naturalists' and Archaeologists' Society closed the outdoor season by a visit to Buxton on Saturday, September 24. The field meetings were well attended during the session, and the introduction of an itinerary for each excursion, detailing the natural history features of the district, was of service. The president, Mr. Charles Bailey, F.L.S., usually gave the address upon the botanical specimens observed. At Buxton, the chairman of the directors of the Winter Gardens conducted the party through the grounds, and undertook to convey to his colleagues the desire of the Society that the county ferns and native phanerogams, so far as they will live at the altitude of the gar-

dens, which are a thousand feet above the sea, should be introduced.

At a meeting of the Norfolk and Norwich Naturalists' Society, held in the Norwich Museum on September 27, Mr. Southwell exhibited, by permission of Mr. T. Ground, of Moseley, Birmingham, a Siberian pectoral sandpiper (*Tringa acuminata*), killed at Yarmouth by that gentleman on August 29, which he believed to be the first European example of this bird hitherto recorded.

THE administrative report of the Marine Survey of India for the official year 1891-92 has been published. Dr. A. Alcock, Surgeon-Naturalist to the Survey, shows that in his department the year has been by no means unproductive. He expresses his belief, however, that the results would be tenfold greater, both from the scientific and from the economic points of view, if, in the survey of inhabited coasts, the naturalist could follow the ship from camp to camp ashore, visiting it at short, convenient intervals for medical purposes, but otherwise devoting all his time to systematic exploration of the grounds worked by the fishermen—grounds of marvellous richness still quite unexplored and unappreciated.

AMONG the animals Dr. Alcock has specially observed is the red ocypodid crab, which swarms on all the sandy shores of India. The bigger of its two chelæ, or pincers, bears across the "palm" a long finely-toothed ridge, and on one of the basal joints of the "arm," against which the "palm" can be tightly closed, there is a second similar ridge. When the "palm" is so folded against the base of the "arm," the first ridge can be worked across the second, like a bow across a fiddle, only in this case the bow is several times larger than the fiddle. The remarkable resemblance of the whole arrangement to the stridulating apparatus of many insects led Prof. Wood Mason some time ago to infer a similarity of function, and he asked Dr. Alcock to observe the crabs, and to listen for the sounds which he supposed them to be capable of making. Dr. Alcock is now able to give facts which establish the truth of Prof. Wood Mason's idea. The sounds can be heard, and their effects seen, if one crab, which may be called the intruder, is forced into the burrow of another, which may be called the rightful owner. The intruder shows the strongest reluctance to enter, and will take all the risks of open flight rather than do so, and when forced in he keeps as near the mouth of the burrow as possible. When the rightful owner discovers the intruder he utters a few broken tones of remonstrance, on hearing which the intruder, if permitted, will at once leave the burrow. If the intruder be prevented from making his escape, the low and broken tones of the rightful owner gradually rise in loudness and shrillness and frequency until they become a continuous low-pitched whirr, or high-pitched growl, the burrow acting as a resonator. Dr. Alcock concludes that the use of the stridulating organ appears to be that a crab, when it has entered its burrow, may be able, by the utterance of warning notes, to prevent other crabs from crowding in on top of it.

DR. FRITZ NOETLING has been investigating the amber and jade mines of Upper Burma, and sets forth the results of his inquiry in the new number of the Records of the Geological Survey of India. The strata in which the amber is found belong to the tertiary formation, probably to the lower miocene. Dr. Noetling does not think that Burmese amber would be received with much favour in Western markets—first, because it does not include the milky-white, clouded variety which has for a long time been so much appreciated in Europe; second, because of its fluorescence. This is the bluish tinge which appears when the amber is looked at under a certain angle—a tinge which is sometimes so strong that fine yellow pieces seem to be of an ugly greenish colour.

DR NOETLING has formed a higher idea of the value of the jade mines of Burma. There are two different groups of jade mines—pit and quarry mines. The former are situated along the bank of the Uru river, beginning at about Sankha village, and extending for a distance of about forty miles farther down. The quarry mines near Tammaw village are situated eight miles west of the Sankha village, on the top of a plateau rising to about 1,600 feet above the level of the Uru river. The Tammaw mines afford the best opportunity for the study of the geological conditions under which the jade is found. It there forms a vein of considerable thickness in an igneous rock of blackish-green colour. The jade is a purely white crypto-crystalline mineral, much resembling the finest marble, containing here and there green specks of various sizes, which form the jade proper. The jade vein is separated from the black rock by a band of a soft and highly decomposed argillaceous mineral. The strike of the vein is approximately north to south, and the dip at about an angle of 20°, varying considerably towards east. There are at least 500 men engaged every season in working the quarry mines at Tammaw. The mining operations are carried on in the rudest fashion. No blasting powder being available, the rock is heated by large fires, and, having cooled down, is broken in pieces by means of enormous iron hammers. The operations in the pit mines are less difficult. The miner simply digs a pit and selects boulders of jade from the stuff dug out. Good pieces of jade are sometimes found in the laterite, which forms beds of varying thickness along the Uru. These pieces have superficially undergone a certain discolouring in such a way that the original green or white is changed under the influence of the hydrated oxide of iron into a dark red colour. Specimens of this kind are generally known as "red jade." Dr Noetling says that the jade mines form a most valuable property. He has no doubt that besides the Tammaw jade vein others will be discovered. We know now that jade is intimately associated with a dark igneous rock (trap), and Burma abounds in rocks of this kind.

MR OTIS T MASON contributes to the latest report of the U. S. National Museum (for 1890) an interesting study of the ulu, or woman's knife, of the Eskimo. The ulu is found throughout the Eskimo region, from Labrador to Kadiak, and consists of a blade and a handle or grip with or without some form of lashing. The blade is either a thin piece of slate ground to an edge, a bit of cherty or flinty rock chipped to an edge, a scrap of steel or iron from wrecks of whaling vessels, or good blades made and sold to the Eskimo by traders who visit their country. The handle varies greatly in material, form, and finish. In form alone the specimens from each typical area are unique. Some of the ulus in the U. S. National Museum are as coarse as savagery could make them, others are very beautiful. The same locality furnishes both and intervening kinds, but some areas supply only coarse work. The problem has to some extent been complicated by white influence. The ulu has survived in civilized countries under two well-known forms—the saddler's knife and the kitchen knife. The saddler thus perpetuates, for cutting leather, an implement designed to be used with skins from which the hair has not been removed. The kitchen chopper is the woman's knife deprived of nearly all its ancient and primitive offices, consigned to a single one, which it scarcely had at the beginning. The saddler's knife may be seen in the hands of leather-cutters represented on Egyptian monuments. An excellent series of illustrations, grouped in accordance with the regions from which the specimens come, adds greatly to the interest and value of Mr. Mason's paper.

It is a common experience in daily life that milk has in itself little or no tendency to putrefaction, and that it may even to some extent preserve certain substances that are readily decom-

posed, such as meat. This property has lately been investigated by Herr Winternitz, in Strasburg. Of the three chief constituents of milk, viz., casein, fat, and milk sugar, the first proved as liable to putrefaction as the meat or pancreas extract experimented with, the fat, too, had no preservative influence. Milk-sugar, on the other hand, in accordance with what is known regarding the power of carbohydrates to retard putrefaction, acted as strongly as cane-sugar. Nothing definite was ascertained as to the nature of this action. It was proved, however, to take place in the alimentary canal as well as outside of the system.

RATS at Milnthorpe, Westmoreland, seem to have found a fresh outlet for their predatory impulses. Mr G. Reade, in a letter quoted in the new number of the *Zoologist*, says that the ripe gooseberries in his garden there were disappearing very rapidly this year, and he supposed that the mischief was being done by blackbirds. However, his attention was called to a large rat taking the berries off with his mouth and dropping them to other rats below. Presently another climbed the tree and helped to gather the berries. In a little time both came down, each with a berry in its mouth, having a curious appearance. Mr Reade saw the performance several times repeated. Then he placed a wire cage under the tree, and in three days caught nine of the intruders.

THE electric light seems to have an extraordinary attraction for lepidoptera. On August 19, as he records in the new number of the *Entomologist*, Mr D. S. Stewart had an opportunity of noting this fact. At the Eddystone lighthouse exhibited in the Botanic Gardens at Old Trafford (the same lighthouse as was shown at the Naval Exhibition), he saw great numbers of moths. Before ascending, he says, one could see them from below, flashing in and out of the rays in hundreds, and when the top was reached, the place was found to be full of them—"some, apparently dazzled by the light, frantically flying in all directions, buzzing and hanging in your face, up your sleeves, down your neck, everywhere. In every sheltered niche and cranny four or five were to be seen together, and especially was this so on the staircase, which was strewn with their partially cremated remains, the result of their all too successful attempts at self immolation."

A VALUABLE paper on the breeding habits, eggs, and young of certain snakes, by O. P. Hay, is printed in the latest volume (xv) of the Proceedings of the U. S. National Museum, and has also been issued separately. Mr Hay notes that, although serpents have made a deep impression on the human mind, very little accurate information has been accumulated concerning some of their habits. His paper embodies the results of a good deal of careful personal observation.

THE Nova Scotian Institute of Natural Science has changed its name to the Nova Scotian Institute of Science, and has secured an Act of Incorporation. It has now begun the second series of its "Proceedings and Transactions," the first part of vol. i having just been issued. Among the papers in this part are "Notes on the surface geology of South Western Nova Scotia," by Prof. L. W. Bailey, "Steam boiler tests as a means of determining the calorific value of fuels," by D. W. Robb, "Analyses of Nova Scotia coals and other minerals," by E. Gilpin, jun., "The Magdalene Islands," by the Rev. Dr G. Paterson, "Notes for a Flora of Nova Scotia," Part I by Prof. G. Lawson.

MESSRS. WILLIAMS AND NOROATE are about to publish a work entitled the "Cry of the Children," by "Free Lance." It deals with education in a wide sense, but more especially it advocates the necessity of a scientific training.

PAR I of a new work on practical physics, by Prof W F Barrett, of the Royal College of Science for Ireland, will shortly be published by Messrs Percival and Co. It will treat of physical processes and measurements, and the properties of matter.

THE University Correspondence College has issued its calendar for 1892-93. The Principal, in his report, shows that the college has been in many ways remarkably successful.

THE calendar of the Imperial University of Japan for 1891-92 affords ample evidence that the authorities of this important institution are doing everything in their power to secure that it shall meet the needs of the present age. We may note that in the college of science the following seven courses, each of which extends over three years, have been established: Mathematics, astronomy, physics, chemistry, zoology, botany, and geology.

IN the last sentence of the fourth paragraph of Lord Kelvin's article on "Generalization of Mercator's Projection Performed by aid of Electrical Instruments" (NATURE, September 22, p. 491), for "three" read "two." For corrections in paragraph 3, and in the last paragraph but one, see article "To Draw a Mercator Chart, &c.," in the present issue.

AN interesting new compound, the silver salt of the little known imide of sulphuric acid,  $\text{SO}_2\text{NAg}$ , has been obtained by Dr Wilhelm Traube, in the laboratory of the University of Berlin, and an account of its properties, together with a considerable amount of fresh information concerning both the amide and imide of sulphuric acid, are contributed by him to the current number of the *Berichte*. Regnault long ago obtained a solid substance, which he regarded as a mixture of the neutral amide of sulphuric acid  $\text{SO}_2(\text{NH}_2)_2$  with ammonium chloride, by leading ammonia gas into a solution of sulphuryl chloride  $\text{SO}_2\text{Cl}_2$  in ethylene chloride.

The separation of the two substances, however, was but imperfectly effected, so that our knowledge of the amide itself is very vague. Dr Traube now shows that the amide may be isolated without difficulty by the following process. The sulphuryl chloride is dissolved in fifteen times its volume of chloroform, which exerts no chemical action upon it, and dry ammonia gas is led through the liquid until the latter becomes saturated. The products of the reaction separate during the passage of the gas in the form of a white solid. The whole product is then agitated with water until the precipitate dissolves, the aqueous solution is separated from the chloroform and afterwards boiled in contact with oxide of lead or silver until all chlorine is removed from it. Upon filtering and evaporating the resulting liquid a syrup is eventually obtained, which only crystallizes with difficulty and would appear to consist of neutral sulphamide  $\text{SO}_2(\text{NH}_2)_2$ . It is an extremely deliquescent substance whose solution in water and dilute acids is not precipitated by salts of barium or by platinic chloride. Only after prolonged boiling with hydrochloric acid does decomposition occur with the gradual deposition of barium sulphate. The effect of boiling in the presence of acids would appear to be its conversion into ammonium sulphate. Sulphamide possesses the power of combining with the oxides of mercury, lead, and silver, to form white solid substances. Thus if mercuric nitrate, lead acetate, or ammoniacal silver nitrate are added to the aqueous solution of the amide these white solid compounds are precipitated. The mercury compound is insoluble in dilute nitric acid, while the lead and silver compounds are readily soluble, forming solutions which are perfectly indifferent to barium salts. It was from the compound containing silver that the interesting silver imide was obtained. Upon heating the silver compound to the temperature

of  $170-180^\circ$  until ammonia ceases to be evolved, and extracting the residue with hot water feebly acidified with nitric acid, the new compound  $\text{SO}_2\text{NAg}$  separates upon cooling in long acicular crystals. Analyses have proved its composition to be that stated, and from its reactions it must be regarded as being the silver salt of sulphimide  $\text{SO}_2\text{NH}$ . The crystals are only soluble with difficulty in cold water, but more freely in hot water and readily in dilute nitric acid. The solution is not precipitated by barium nitrate. Even after removal of the silver by means of hydrochloric acid barium salts yield no precipitate, indeed, it requires long boiling with concentrated acid to effect any precipitation. It would appear that the solution left after removal of the silver contains sulphimide itself, and Dr Traube is continuing his experiments with a view to the isolation of the latter compound.

THE additions to the Zoological Society's Gardens during the past week include a Grivet Monkey (*Cercopithecus griseo-auratus* ♀) from South Africa, presented by Mr W. Howard; a Lark (*Hauda celizor*) from China, presented by Mr Gervase F. Mathew, R.N., F.R.S.; two Common Kestrels (*Tinnunculus alaudarius*), British, presented by Mr L. Bergasse; a Herring Gull (*Larus argentatus*), British, presented by Mr H. H. Johnson; a Turtler (Ivory) (*Sphenodon punctatus*), from New Zealand, presented by Capt G. Eriksen; four Smooth Snakes (*Coronella levis*) British, presented by Mr E. Penton, F.R.S.; six American Green Frogs (*Rana halecina*), four Noisy Frogs (*Rana clamata*), from Canada, purchased; one Concave casqued Hornbill (*Dichoceros buroeri*), from India, received in exchange; three Wild Swine (*Sus scrofa*) born in the Gardens.

#### OUR ASTRONOMICAL COLUMN

COMET BROOKS (AUGUST 27, 1892) — *Astronomische Nachrichten*, No. 3119, contains the elements and ephemeris of Brooks's comet calculated by Dr. Ristenpert, assuming an elliptical orbit and the unit of brightness on August 31.5 as the unit of Br. —

##### Elements

$\Gamma = 1892 \text{ Dec } 28 \ 2870 \text{ M.T. Berlin}$

$$\omega = 252^\circ 4' 23.0''$$

$$q = 264 \ 34 \ 45 \ 3$$

$$i = 24 \ 43 \ 17 \ 1$$

$$\log q = 9.994136$$

##### Ephemeris for 12h Berlin M.T.

**NOVA AURIGÆ**—In some further notes that we have referring to the brightness and the spectrum of the Nova, we find that most observers estimate the star's magnitude to lie between 10 and 10.5. Herr Belopolsky, who has examined the star spectroscopically, has been able to see one or two lines, a later estimation of the brightest gave a wave length of 501, while the second line proved too variable in brightness to allow of a sufficiently correct measurement.

To *Astronomische Nachrichten*, No. 3118, Mr H Seelinger contributes a very important article, in which he suggests an hypothesis which may be said to approach that put forward by Mr Lockyer some time ago. He assumes (and a very fair assumption too) that the cosmos contains innumerable more or less elongated forms of very thin and small particles, and that the Nova was produced by a body rushing into one of these, so to speak, clouds. On entering this cosmical cloud, at once there would be a condition for producing heat, and therefore light, and we have only to imagine the cloud to be of varying thicknesses to account for the peculiar fluctuations which attended the light of the Nova. That such a case should take place seems in itself more probable than that of two bodies passing very near one another, and we already know that such streams as suggested do exist. Our November shower, for instance, is such a swarm, only on a scale very much smaller than that inferred above.

#### GEOGRAPHICAL NOTES

UNTIL recently the Samoan calendar corresponded with the Australian, but on July 4 last a change was made by order of King Malietoa. Tuesday, July 5, was reckoned a second time as Monday, July 4, thereby coming into harmony with the American and European reckoning. Samoa, lying to the east of 180°, had retained the old system of time, superseded by the general acceptance of that meridian as the line at which the date is rectified by vessels at sea.

CAPTAIN LUGARD reached London from Uganda on Sunday night. It is gratifying to know that his three years' residence in equatorial Africa, and the severe strain of recent events, have not told adversely on his health. He will probably communicate the important geographical results obtained by him to a special meeting of the Royal Geographical Society in November.

THE arrangements for the next session of the Royal Geographical Society present several new features. In addition to the ordinary meetings it is proposed to give a special series of Christmas lectures to young people, to be followed by a course of ten weekly educational lectures, specially adapted for teachers, by Mr H J Mackinder. The ordinary meetings as provisionally arranged begin on November 14 by a paper on his proposed North Polar expedition by Dr Nansen. Mr Joseph Thomson will follow with an account of his expedition to Lake Bangweulu. Captain Bower will describe his journey across Tibet, and Captain Lugard will recount his discoveries in equatorial Africa. Prof. Milne and Mr Savage Landor have promised papers on Yesso, Major Rundell on the Suiyün China, Mr H O Forbes on the Chatham Islands, and Captain Gallwey on Benin. It is hoped that Mr Conway will return to describe his adventures in the Karakoram mountains. Apart from the records of travel to which the attention of the Society in its ordinary meetings has usually been mainly devoted, there will be papers dealing with the more general and scientific aspects of Geography. The Prince of Monaco will probably describe his experiments on the Atlantic currents, Sir Archibald Geikie will lecture on types of scenery, Prof. Honney on the work of glaciers, Mr J Y Buchanan on the windings of rivers, and Dr Schlichter on his new photographic method of determining longitude.

THE last number of *Petermann's Mitteilungen* contains an important paper by Dr Alois Bludau giving the co-ordinates for Lambert's equivalent area azimuthal projection of the map of Africa. An outline of the continent on this projection, the central point of which is on the equator in 20° E long., shows the remarkable suitability of the map for representing Africa, the distortion being inappreciable.

NO. 1197, VOL. 46]

#### MAGNETIC INDUCTION<sup>1</sup>

THE lecturer remarked that it was no less than forty-five years since the magnetic properties of materials had formed the subject of an evening discourse before the British Association. At the Oxford meeting in 1847 the lecturer was Michael Faraday, who had only a little while before made his great discovery of diamagnetism and been led to the splendid generalization that all substances are in one way or other, and in greater or less degree, susceptible of magnetic influence. And it was an interesting coincidence that in the same year, partly indeed at that same Oxford meeting of the Association, the foundation of the modern mathematical treatment of magnetism had been laid by that infant phenomenon, whom in the vigour of his maturity we were now learning to call Lord Kelvin. Discarding the arbitrary hypotheses of earlier theoretical writers, Lord Kelvin, then a stripling at Cambridge, had proceeded to give mathematical expression to the observations and intuitions of Faraday. In recent years the science of magnetism had advanced fast, keeping pace with the advance of its industrial applications. In common with other branches of electricity it had discovered the advantage of being useful. The debt which practice owed to science had been repaid with interest. In other departments of science it might be true that there were devotees whose chief pride in their work lay in their reflection that it could never be of any use to anybody; this temper of mind was not possible to an electrician. The language of electricians had passed with bewildering rapidity into Acts of Parliament and provisional orders of the Board of Trade, and the demands of industry had stimulated discovery and fostered exactness in measurement. It was the beneficent reaction of practice on science that had enabled the great work of the Electrical Standards Committee of the British Association to be brought to a successful issue. As a fruit of that work electricians were in high hope that this Edinburgh meeting would result in an international agreement with regard to the electrical units, so that whatever the Great Powers might find to differ about they would at least be of one mind as to the magnitude of the volt, the ampere, and the ohm. In the co-operation of Prof. von Helmholtz on the part of Germany, and of M. Mascart on the part of France, with Lord Kelvin and Rayleigh and their English colleagues, there were surely the elements of a Triple Alliance which should secure to the electrical world peace, not only with honour, but with precision.

The lecture of Faraday in 1847 had dealt with the condition induced by magnetic force in matter which was not ordinarily magnetic. Substances were broadly divisible into two classes, those which were strongly susceptible to magnetic influence and those that were only very feebly susceptible. The latter was by far the most numerous class, and it was with it that Faraday dealt in his lecture. The strongly magnetic substances were iron and its various derivatives, which passed by the general name of steel, also nickel and cobalt. A recent discovery by Prof. Dewar seemed to require that oxygen, in the liquid state, should be added to this list. The lecturer proposed to confine his attention to the phenomena of magnetization which were exhibited by the strongly magnetic metals. Let any one of these metals be submitted to the action of a magnetizing force such as would be produced if an electric current were passed through a coil of insulated wire surrounding the metal. As the current was gradually increased, the magnetization passed through three stages. It began very gradually, at first, while the current was still weak, there was but little magnetism developed. Then a stage came on in which the magnetic state was acquired with great rapidity; a small increase in the current now caused an enormous gain of magnetism. Finally, the process passed into a third stage, when the magnetism was again acquired slowly, and however much the magnetizing current was increased it was found to be impossible to force the magnetism to exceed a certain limiting value. This was the phenomenon of magnetic saturation. Recent researches had given definiteness to the rather vague idea which used to be expressed by this phrase, and it was now known not only that a limit existed, but what its values were in the several magnetic metals. The lecturer illustrated the three stages in the magnetizing process by means of the lantern, exhibiting curves which showed the connection between mag-

<sup>1</sup> Abstract of an evening lecture delivered before the British Association, at Edinburgh, August 8, 1892, by J A Ewing, M A, F R S, Professor of Mechanism and Applied Mechanics, Cambridge University.

netism and magnetizing force, and pointed out that in special cases the three stages became extraordinarily distinct. Curves of the same kind were used to show what happened after a magnetizing force had been applied, if it were withdrawn or varied in any way. The magnetism in all cases tended to lag behind when the magnetizing force was varied, and hence these curves in any cyclic process became loops enclosing a certain area. It had been proved that this area served to measure the energy expended in carrying the substance through a cyclic magnetizing process, the reason why energy had to be spent being the tendency which the magnetism always had to lag behind the force that was operating to change it. To this tendency he had given the name "hysteresis," a term which was already of formidable significance in the ears of practical electricians. For the existence of hysteresis was the chief reason why the transformers which were used in alternate current systems of electrical distribution absorbed wastefully a considerable amount of power. The iron core of a transformer was being carried through a cycle of magnetization from a positive to a negative value and

Weber postulated an arbitrary directing force, which tended to hold them in their original direction. The lecturer proceeded to show by means of experiments conducted on the projecting table of the lantern, and shown on a large scale on the screen, that no arbitrary directing force was necessary. The mutual actions of the molecular magnets on one another supplied all the control that was required. It accounted completely for the three stages of the magnetizing process and for all the phenomena of hysteresis. It accounted also for the effects which were found to be produced by mechanical vibration and mechanical strain. Experiments were made exhibiting the breaking up of molecular groups, bound together by their mutual forces, under the influence of a gradually increased external directing force. In these experiments models were used, consisting of a number of small magnets, pivoted like compass needles on fixed centres, and arranged on the horizontal table of a large projecting lantern. A pair of coils placed one on either side of the group supplied deflecting force, and as the current in these was gradually increased the three stages of the magnetizing

FIG. 1.—Prof. Ewing's Magnetic Curve Tracer. General view of apparatus.

back again some 80 or 100 or 120 times a second, and every one of these periodic reversals of magnetism implied a waste of energy, which went on even when no useful current was being drawn off. It was a question of considerable practical interest, whether the amount of work wasted on the iron of a transformer was the same per cycle at high speeds of reversal such as were usual in practice, as it was in the slow speed laboratory experiments, by the help of which these cyclic curves had been drawn.

The lecturer proceeded to give some account of molecular theories which had been framed to account for the characteristics of the magnetizing process. It was suggested, originally by Weber, that the molecules of iron are always little magnets, and that when the iron, as a whole, is not magnetized, it is because as many of the molecular magnets are facing one way as another. According to this view the process of magnetization consists in turning the molecular magnets round, so that they face, more or less, one way. When a very strong magnetizing force is applied, the molecules are forced all to face one way, the piece is then saturated. To explain why they did not at once turn round completely when any magnetizing force was applied,

process and the phenomena of hysteresis exhibited themselves in the manner in which rearrangement of the elementary magnets composing the group took place. In some of the models the magnets turned under water, so that their vibrations were rapidly damped out. Slides were also shown which gave some of the results of observations recently made in the lecturer's laboratory by Miss Klaassen, of Newnham College, which demonstrated an extraordinarily close agreement between the phenomena noticed in the magnetization of actual iron and those presented by a model consisting of groups of little pivoted magnets. Even the less conspicuous features of the actual process were reproduced in the model with a fidelity which went far to confirm this molecular theory of magnetism. It was shown, for instance, that the model reproduces a phenomenon familiar in real iron, namely, the tendency which magnetic changes exhibit to be imperfectly cyclic, under cyclic changes of magnetic force, until these are repeated several times, and also that in the model, just as in real iron, this tendency disappears if a process of demagnetizing by reversals of gradually diminishing magnetic force has been previously gone through.

The lecturer proceeded to show in action a novel apparatus he had devised to exhibit the magnetizing process in actual iron, and to test the magnetic qualities of metals. This magnetic curve tracer (Fig. 1) consists of two wires—AA and BB—tightly stretched in two narrow gaps in the magnets DD and C respectively. The magnet C consists of a piece of slotted iron tube, which is kept constantly magnetized. Consequently, when a variable current passes along the wire BB that wire sags out or in, giving azimuthal movement to a mirror F. The variable current which passes through the wire B serves to magnetize the electromagnet DD, which consists of two bars of the iron to be tested, sunk into fixed pole pieces and united at the back end by a short yoke-piece of soft iron. When the magnetism of DD varies it causes the wire AA, which carries a constant current, to sag up and down, and this gives movement in altitude to the mirror E. The mirror is pivoted on a single needle point, and has freedom to respond to the motion of both the stretched wires AA and BB. Since its azimuth movement is proportional to the magnetizing current, and its altitude movement is proportional to the magnetism acquired by DD, the mirror causes a spot of light reflected from it to trace out the ordinary magnetization curve, showing the relation of magnetism to magnetizing force. By making the variable current change continuously from a positive to an equal negative value and back again, a complete cycle of magnetization was performed in the bars DD, and in this way the magnetic characteristics of the bars could be completely determined in a few seconds. The lecturer proceeded to test in succession a pair of wrought-iron bars, then a pair of hard steel bars, and finally a pair of cast iron bars, causing the cyclic curve for each material to be automatically drawn on the screen, on a very large scale, to exhibit the features of difference. The mirror and other moving parts of the apparatus were so dead bent that it was possible to go through a cycle ten or even twenty times a second without experiencing inconvenience from the effects of inertia. In that case, however, the iron must be laminated to avoid sluggishness in the magnetizing process itself. Using an instrument with a magnet consisting of a split ring of iron wire, a process of periodic reversal was performed at a speed sufficient to make the curve traced out by the light spot become a continuously luminous line (Fig. 2), and the process

FIG. 2.—Photograph of Magnetization Curve traced by Prof. Ewing's Magnetic Tester

of demagnetizing by reversals was illustrated by making this curve gradually contract itself to zero by slowly reducing the strength of the current while the rapid periodic reversals were continued. The effect was also shown of superposing one

periodic alternation upon another, by which loops resembling those of Fig. 3 were drawn. The lecturer pointed out that these experiments went some way towards answering the question whether the magnetizing process went on in the same way, and involved the same dissipation of energy through hysteresis, at

FIG. 3. Photograph of Magnetization Curve with Loops

high speeds as at low speeds. He concluded by expressing the hope that this apparatus would prove of some service to the builders of dynamos and transformers by giving them a novel means of testing the magnetic properties of their iron with great completeness and in a manner sufficiently simple for workshop use.

#### BOTANICAL PAPERS AT THE BRITISH ASSOCIATION

IN our account of the proceedings of Section D of the British Association (NATURE, August 25, p. 403), we promised to refer on a later occasion to some botanical papers which could not then be noticed. The following are abstracts of several of the more important of these papers—

"Observations on Secondary Tissues in Monocotyledons," by Dr. Scott and Mr. Brehner. (1) The secondary tracheides in *Dracena* and *Yucca* develop simply by the enormous growth in length of single cells, the nuclei remaining undivided, and not by cell fusion, as many authors suppose. (2) The cambium in the roots of many species of *Dracena* does not appear in the pericycle, but in the cortex outside the endodermis. The secondary growth starts from the insertion of a rootlet, the cambium being pericyclic near, and cortical at a greater distance from, the rootlet. (3) Description of secondary thickening in *Iridaceae*.

"On the Simplest Form of Moss," by Professor Goebel. The author stated that previous researches had led him to the conclusion that mosses and ferns did not stand in direct genetic relationship with each other, but that they are descended from simple alga-like forms, in fact the mosses pass through a developmental stage so alga-like in appearance that it was formerly described as an algal genus *Protozema*. If the sexual organs of the moss arose not on the stem but on the protonema, we should have the sexual generation agreeing perfectly with the filamentous algae. The leaves of the moss would then arise originally as protective organs for the antheridia and archegonia. This, up to the present, hypothetical form, actually occurs in *Buxbaumia*. In this moss the antheridia occur at the end of a protonema-branch, surrounded by a mussel-shaped envelope. The female plant is more highly organised, but is still much simpler than in other mosses. These and other observations lead Prof. Goebel to the conclusion that *Buxbaumia* is a very ancient form which stands in the closest relation to the lower algae.

"On the cause of Physiological Action at a Distance," by Prof L. Errera (Brussels). The author referred to Elfvig's observation, that sporangium bearing filaments of *Phycomyces nitens* are attracted by iron, zinc, aluminium, and various organic substances, such attractions not being due to gravitation, light, moisture or contact, but to physiological action at a distance, as Elfvig terms it.

The author has made numerous experiments which tend to show that the attraction is really hydrotropic, the filaments being attracted by hygroscopic and repelled by non hygroscopic substances, for example —

Any modification of iron which lessens its capacity of rusting at the same time diminishes its attraction on *Phycomyces* thus, polished steel scarcely attracts, and nickled steel does not do so at all.

China clay, which is very hygroscopic, attracts energetically, while china exhibits no attraction. These experiments succeed also in a saturated atmosphere, which shows that hydrotropism is not due, as generally supposed, to differences in the hygrometric state of the air.

"Notes on the Morphology of the spore bearing members in the Vascular Cryptogams," by Prof F. O. Bower. The author explained by the help of a large series of diagrams his views already laid before the Royal Society, as to the homology of the fertile frond of *Ophioglossum* with the sporangium of *Lycopodium*. In support of the probability that the former may have been derived from some such type as the latter, by a process of partial sterilization of the sporogenous tissues, he adduced facts relating to *Isotetes* and *Lepidodendron*, both of which show a sterilization of parts of the potential sporogenous tissue in the form of trabecule in the sporangium.

Mr C. I. Drury sent in a communication, which was read and remarked upon by Prof Bower. It related to a new example of apospory found in a young fern seedling, of which the second frond bore upon its margin a number of prothalloid growths. The occurrence of aposporous development at so early a stage in the development of the sporophyte had not hitherto been recorded.

"On the arrangement of buds in *Ilex* Minor," by Miss Nina F. Layard. The object of a series of observations made on budding duckweeds, was to ascertain whether any fixed rule is followed, both in the arrangement and order of production of the buds.

Prof F. Schmitz read a paper on tubercles on the thallus of *Cystodinium purpurascens* and other red seaweeds. The tubercles are constantly inhabited by bacteria, and appear to arise in consequence of infection by these organisms.

"*Calamostachys Binneyana*, Schimp," by T. Hick. The object of the paper is to revise and extend our knowledge of the structure of this fossil fruit in the light of a number of preparations which have not been previously described. The central part of the axis, formerly described by Carruthers and Williamson as vascular, the author finds to be cellular, thus removing the chief ground for Williamson's reference of the spike to the *Lycopodiaceæ*. Round the cellular pith there are (usually) three primary vascular bundles, which are reduced to the condition of those met with in *Equisetum*, and the young shoots of *Calamites*, i.e. to as many carinal canals with annular and spiral vessels adhering to the margin.

As to the affinities, the conclusion arrived at is that the fruit is that of some form of *Calamites*—as Carruthers maintained long ago—and perhaps that of the type known as *Arthropitys*.

"Myeloxylon from the Millstone Grit and Coal-Measures," by Mr A. C. Seward. Specimens of Myeloxylon (Brong.), (*Stenzelia* (Gopp.), *Myelopteris* (Ren.)) were described from a limestone of Millstone Grit age in North Lancashire, their minute structure being fairly well preserved, and showing collateral bundles, gum canals (?), and the hypodermal tissues characteristic of the genus. A much more perfect example from the Binney collection was referred to, of coal-measure age, in which not only the xylem but also the phloem elements had been mineralised in an unusual state of perfection.

It was pointed out that in the Binney specimen the position of the Protoxylem on the Phloem side of the bundles was clearly shown both in transverse and longitudinal sections. The affinities of Myeloxylon with Cycads and Ferns were briefly discussed, and the conclusion arrived at that this extinct genus, although differing in certain particulars both from Cycads and Ferns, should be placed much nearer the former than the latter.

## SCIENTIFIC SERIALS

THE *American Meteorological Journal* for September contains the conclusion of "Objections to Faye's Theory of Cyclones," by W. C. Moore. Only a few of the more essential characteristics of cyclonic storms have been considered, but from these the author concludes that it is evident that the generally accepted theory of convectional motion gives a more satisfactory explanation of the various phenomena than the theory advanced by M. Faye—"Changes of Plane of the Mississippi River," by Prof T. Russell. The author analyses a report by Colonel C. R. Suter, of the Mississippi River Commission relating to the improvement of the river and methods of preventing overflow—"Thunderstorms in New England during the Year 1887," by R. de C. Ward. The difficulty of predicting thunderstorms is shown by the fact that in New England in 1887 the majority of storms occurred in the south-eastern quadrant of cyclones, while in the previous year the majority occurred in the southern or south-western quadrant. Only 40 per cent of the summer thunderstorms of 1887 occurred in the southern part of cyclonic storms, while in the previous year the number was 70 per cent—"Weather Forecasting at the Signal Office, June 30, 1891," by Prof H. A. Hazen. At this date the weather service was transferred to the Agricultural Department, and the author has given the results of his experience by laying down certain fundamental rules which would be of service to a beginner in the work, as it has sometimes been suggested that it would be almost impossible for a forecaster to impart his knowledge to another—"The Effect of Topography upon Thunderstorms," by R. S. Tarr. The author's observations have led him to believe that topography has a decided effect upon the path of thunderstorms when they are beginning. When, however, the storm has assumed more than local proportions, topography has in all probability very little effect upon its motion.

## SOCIETIES AND ACADEMIES

### PARIS

Academy of Sciences, Sept. 26.—M. Duchartre in the Chair.—On the white rainbow, by M. Mascart. A new mathematical treatment of the subject shows that the diameter of drops giving the most perfect achromatism is  $29.17\mu$ . With drops of  $30\mu$  the rainbow will appear the whiter, the more the apparent diameter of the sun hides the excess of blue intermediate between the achromatised points, as well as all the supernumerary arcs, by the superposition of several systems of fringes, so that there is only left an exterior border slightly tinged with red. The same will apply to drops slightly different in one sense or the other, but the achromatism persists longer if the diameter diminishes. The observation of clouds and logs has shown that the diameter of the drops varies from 6 to  $100\mu$ , the last beginning to fall as rain. Thus the circumstances favouring the production of white rainbows are of very frequent occurrence.—Places of origin or emergence of the great cholera epidemics, and particularly of the pandemic of 1846-49, by M. J. D. Tholozan. From Dr Arnot's communications to the Physico-medical Society of Bombay, from the documents of the Medical Committee of Bengal, and from the testimony of Ferrier, who was travelling in Afghanistan at the time, it is evident that the cholera epidemic which invaded Europe and America in 1847, 1848, and 1849 originated in Bokhara, whence it spread to Afghanistan and India, as well as westward. Bokhara, Samarkand, Balkh, and Kunduz were attacked at the end of the summer of 1844, Herat and Kabul in October, Jellalabad at the beginning, and Peshawar at the end of November. In the following summer the epidemic proceeded steadily eastwards into the "endemic area," reaching Jhelum and Lahore in May, 1845, Meerut in August, and Delhi and Agra in October, at the same time passing down the Indus to Kurrachee, and westwards to Meshhed, whence it proceeded in 1846 to Asterabad, Teheran, Reht, and Baku. A similar example of an eastward progress of cholera occurred in 1865, when the great epidemic of Mecca, after having invaded Mesopotamia and Transcaucasia, spread to Teheran, and took the easterly route by Khorassan. The writer expresses his firm conviction that the points of emergence of the choleraic epidemics must be considered as their points of origin. The idea that the different pandemic manifestations of cholera which

have depopulated Europe must have invariably come direct from India is no longer tenable. For Europe alone, two striking examples, in 1852 and 1869 respectively, have formally demolished the theories which regarded only things coming from the East as bearing any danger of contamination. The epidemic of 1852 came from within Poland and Germany. That of 1869-73 repeated the same things in Ukraine. Nowadays, when these facts have taken their place in science, some minds seek to diminish their importance by pointing out that these epidemics revived some previous epidemics which had their origin in India. But that which makes the spreading epidemic or the pandemic is the revival of the choleraic principle or germ with all its original attributes. Even in India similar revivals perpetuate the annual endemic, and the epidemics which appear every three, four, or five years. This is the main fact which governs the entire history of cholera, and upon which micro biological research must proceed. What difference of morphology, of virulence, or of reproductive faculty is there between the germs of the epidemics which die out at their origin, and those of the epidemics which revive several times, and can invade the whole world without proceeding from India?—Application of a conventional system of rectangular co ordinates to the triangulation of the coasts of Corsica, by M. Hatt. The trigonometrical network drawn for the hydrographic mapping of the coasts of Corsica describes a closed curve. The employment of the conventional system, which transforms into rectangular plane co ordinates the polar co ordinates reckoned on the sphere round an origin, offers numerous advantages. The suppression of the sphericity permits the application of processes of calculation which have been dealt with in a preceding communication on rectangular co ordinates. On this account it was interesting to test on a larger scale the methods which had only been utilised for the determination of secondary points. The experiment has given satisfactory results, and exhibits the practical advantages of the new system of co ordinates and the methods of calculation. K being the length of the geodetic line joining a point to the origin, and Z the angle made by this line with a fixed direction, the conventional co ordinates are  $x = K \sin Z$  and  $y = K \cos Z$ . These assumptions permit the rapid and easy calculation of tables of corrections.—On a new hydro carbon, suberene, by M. W. Markownikoff.—Action of piperidine and pyridine on the haloid salts of cadmium, by M. Leopold Hugo.

## SYDNEY

Royal Society of New South Wales, June 1.—General Meeting.—Prof. Warren, President, in the chair.—The following papers were read.—Oceanic philology, by Sidney H. Ray, a determination of the magnetic elements at the Physical Laboratory, University of Sydney, by S. Coleridge Parr, on certain geometrical operations, by G. Fleury, analyses of the well, spring, mineral, and Artesian waters of New South Wales, and their probable value for irrigation and other purposes, by John C. H. Mingaye, remarks on the large sunspots visible at the present time, by H. C. Russell, F.R.S.

July 5.—Chemical and Geological Section.—Prof. Liversidge, F.R.S., in the chair.—The following papers were read.—Microscopic structure of some intrusive rocks in the neighbourhood of Sydney, by Rev. J. Milne Curran, notes on the occurrence of platinum and its associated metals in the Richmond River sands, also in lode material in the Broken Hill district, by John C. H. Mingaye.

July 6.—General meeting. Prof. Warren, President, in the chair.—Paper read.—On the ventilation of sewers and drains, by J. M. Smail.

July 15.—Medical Section.—Dr. Friaschi in the chair.—Paper read.—Recent work on the pathology of cancer, by Dr. G. E. Rennie.

August 3.—General Meeting.—Prof. Warren, President, in the chair.—The following papers were read.—Flying machine work, and the  $\frac{1}{4}$  I.H.P. steam motor weighing  $3\frac{1}{2}$  lb., by L. Hargrave. The paper described the experimental work carried out by the author during the past twelve months. A compressed-air-driven flying-machine (No. 16) had no less than twelve trials, on one of which it flew 343 feet, the speed being a little over ten miles per hour. On the first trial it was fitted with a bi-plane, which was found to be a very stable form. Some curious experiments with a segment of a hollow cylinder were recorded. A description was given of a steam engine and boiler for a flying-machine, the total weight of which is  $3\frac{1}{2}$  lb., in-

cluding fuel and water. The indicated horse power developed was 169. Nine detail drawings were shown, including those of an air pump and small-pressure indicator. On the venom of the Australian black snake (*Pseudechis porphyriacus*), by C. J. Martin, Demonstrator of Physiology in the University of Sydney, and J. McGarvie Smith.

## VIVISECTION AT THE CHURCH CONGRESS.

THE attitude of the Church towards science at the present day shows a healthy spirit of tolerance. It fully recognizes that research in physical science is the very embodiment of the seeking after truth, and that the proper exercise of faith is consonant with an attitude of expectancy. This year, however, has seen an attempt, led by Bishop Barry, to disturb this harmony and to create an exception, namely, in the case of scientific research in Biology, whether of normal structure as physiology, or of abnormal, as pathology. At the Church Congress last week the following was referred for open discussion at the instigation of Bishop Barry, who, however, wished, it is stated, to have had a much more sweeping theme presented—

"Do the interests of mankind require experiments on living animals, and, if so, up to what point are they justified?"

There was here presented to the Congress the twofold aspect of the question—utilitarian and moral—the obvious desire of the Subjects Committee being that they should thus have laid before them on these two points the evidence of the usefulness of scientific experiments on living tissues, and the evidence that such research is consonant with morality.

To all scientific men, even if not biologists, there is no need of evidence that experiments on living tissues are necessary to the progress of physiology and pathology. As Mr. Horsley showed in his speech, this position is *a priori* established, since the processes of life are chemical and physical in nature, and can only therefore be advanced by experimental observation whether in the laboratory or by the bedside. It seems, by the way, to have escaped the notice of all the speakers that every new clinical fact is as much the outcome of "experimental" observation as any note made in a laboratory. We would lay stress on this since not only do some dignitaries in the Church but even a few medical men seem to think that clinical discoveries are the result of inspiration, and not the outcome of trying this or that modification of factors and noting the subsequent effects. However, if the Church Congress wanted facts they were supplied in overwhelming degree, and not only facts on the utilitarian side but also many—some unexpected to judge by the excitement produced—on the moral condition of anti-vivisectionists and their beliefs. Putting aside for a moment the utilitarian side of the question, it is doubtful whether the moral responsibility of anti-vivisectionists has ever been more freely exposed to view. After Dr. Wilks had revealed the inconsistency of the agitators and their free use of animals (without anaesthetics) for their own ends, Mr. Horsley probed the consciences of the bishops by pointing out that "it has always been a matter of the utmost surprise to the medical profession that educated men in positions of the gravest moral responsibility like

bishops should have in this matter descended to receive the information they require from sources of notoriously tainted character, rather than by seeing for themselves in our University laboratories what scientific experiments are in reality."

It is certainly a very fair question to ask of Bishops Barry and Moorhouse—What right had they to lend their help to any cause, however righteous it may appear to them, unless they have made a *bona-fide* effort to hear both sides? Has Bishop Barry visited the Physiological Laboratory at Oxford, or Bishop Moorhouse that and the Pathological Laboratory at Owens College? And if not, why not? Most especially ought such care to have been exercised in the case of anti-vivisectionism, since the leaders of that party have attacked not merely individuals, but the whole medical profession as "murderers," "torturers," &c, and have accused them of the grossest cruelty and self-seeking. The bishops referred to have, it is to be feared, forgotten that their office is a very reverend one, not to be lightly used to help any and every alleged reform, and above all not to be used as a means of unfounded denunciation of what Mr. Horsley truly calls an honourable, earnest, and hard-working profession.

It is difficult to see on what possible ground Bishop Barry can defend his use of the expressions "arrogance," "physiological insolence," when he applies them, as he has done, to the simple statements of fact which have been formulated into the following resolutions, the first passed at the International Medical Congress of 1881, and the second at the recent meeting of the British Medical Association at Nottingham.

(1) "That this Congress records its conviction that experiments on living animals have proved of the utmost service to medicine in the past and are indispensable to its future progress. That accordingly, while strongly deprecating the infliction of unnecessary pain, it is of opinion, alike in the interests of man and of animals, that it is not desirable to restrict competent persons in the performance of such experiments."

(2) "That this general meeting of the British Medical Association records its opinion that the results of experiments on living animals have been of inestimable service to man and to the lower animals, and that the continuance and extension of such investigations is essential to the progress of knowledge, the relief of suffering, and the saving of life."

We are glad to see that these unanimous resolutions were read to the Church Congress and appreciated by the audience at their proper value and not according to the estimate of Bishop Barry. Similarly, men of science may not only ask whether Bishop Barry was a moment justified in speaking of physiological research as "cruelty" and "demoralization" while ignorant of the real facts, but they certainly have the right to demand that, should he fail to respond to the challenge offered him by Mr. Horsley, and substantiate his grounds for making these assertions, he should withdraw from the agitation (which has, we suspect, only injured his reputation), and make a free and ample apology.

In the same manner also we would call upon Canon Wilberforce to retreat from the unworthy position into which he has been thrown by the force of feeling uncon-

trolled by reason, and not to make the wrong he has done to science greater by continuing to persist in it regardless of the published demonstration of his error

One curious feature of the whole popular view of the anti-vivisectionist campaign is the general belief in the good faith of Miss Cobbe. To men of science her methods have been familiar ever since the commencement of the agitation, and more especially since they were clearly displayed in the published trial of Adams v. Coleridge. By the general public, however, she was regarded as a fanatic, but trustworthy. After this latter-day exposure at Folkestone to which she has been subjected we hope that such credulity has at last seen its end, for by the production of Miss Cobbe's latest book, "The Nine Circles," and by comparing it with the originals of the scientific papers from which her statements were alleged by her to be taken, Mr Horsley had no difficulty in convincing the Congress that her statements of facts can no longer be relied upon.

It is an old story that a lie dies hard, but die it does at last, and the proceedings of the Church Congress have greatly accelerated the end.

Nothing can do this better than for scientific investigators to patiently instruct the public. At the Church Congress this heavy task fell on Dr Ruffer, who by way of answer to the vague rhetoric of the Bishops, piled fact upon actual fact until his audience [showed] how they welcomed the statements of truth as a counterpoise to Episcopal excommunication.

The painful position of medical men who can be found willing to sanction such an agitation was well exhibited by the action of Mr Lawson Tait, who having publicly charged Church Congress officials with excluding him from the meeting, was positively proved to have withdrawn himself, the withdrawal being contained in his letter read to the Congress by the chairman of the Subjects Committee, the Bishop of Dover.

Lastly, on the broad question of utility, no member of the Church would, we are sure, feel justified in contravening the view that the general regard shared by all Englishmen, and expressed in the above-mentioned resolution of the International Medical Congress, for the proper, that is, humane, use of animals, is ample surety that whether for the sake of food or pursuit of knowledge, the object is obtained at a minimum cost of pain.

The most extraordinary illogicality was displayed on this very point by Bishop Moorhouse, of Manchester, for while declaiming against the killing of animals to gain knowledge, he clamoured for liberty to destroy any number to preserve the volume of his voice.

But if we were to speak of the illogicality of the anti-vivisectionists there would be no end, seeing that as they do not or will not learn the truth, they live in a circle of contradictions. Suffice it to say, that we believe the open discussion of the subject at the Church Congress will do more than anything to show the public that the feeling exhibited by the anti-vivisectionists is one of unmitigated hostility to science, and not one of genuine anxiety for the humane treatment of animals devoted to the service of man.

#### THE NEW VOLUME OF WEISMANN

*Essays on Heredity* By Dr A Weismann Authorized Translation Vol II Edited by E B Poulton, F.R.S., and A E Shipley (Oxford Clarendon Press, 1892)

IN this second volume of the new edition of Dr Weismann's essays there are brought together four essays which did not appear in the first edition, they are in a convenient form, well translated, and well printed.

Nothing is more curious than the public appreciation of Weismann's essays, for in them is no trim, nicely balanced, carefully elaborated statement of his biological theories. The successive essays appear as they were published. You have the theories in their making, stretching from essay to essay, alive, contradictory, disjointed. This historical method of publication is a thing to delight the student of biology, but, one had thought, a torture to the precisian and caviare to the general, yet the public continue to buy, discuss, and no doubt read his works.

In "Retrogressive Development in Nature," Dr Weismann describes cases of vestigial organs or rudimentary functions. To explain the occurrence of these, the transmission and accumulation of degenerate characters produced by disuse is unnecessary. In every organ, as in every animal, variations occur, in every generation unsuitable variations are weeded out, and so the organ or the animal remains adjusted to its environment, or becomes more perfectly adapted to it. But when a change of habit or of environment occurs, as when an eved animal takes to living in dark caves, or when an animal that has been saving its life by swiftness comes into a region devoid of enemies, the less far-seeing or the less swift are not more quickly killed than their better endowed neighbours. So far as sight or swiftness are concerned, a condition of panmixia occurs, and the organs of sight and flight slowly degenerate.

The argument in "Thoughts on the Musical Sense in Animals and Men" is subtle, ingenious, and less familiar. In insects and birds males are the musicians, and sexual selection is a sufficient explanation, but it is not so in man. However, in the mammalia the organ of hearing is remarkably developed. In the auditory organ of a rabbit there are structural arrangements for nearly two thousand note sensations, while a concert grand piano contains only eighty-seven different notes. For the needs of life, the thousand gradations of sound in the woods and the field, of the hunter and the hunted, the mammalian organ is adapted. Music itself is an invention, and from the rude melodies of primitive man to the art of Beethoven and Chopin, it has been progressively developed as the intellectual faculties have been developed.

The third essay, "Remarks on certain Problems of the Day," is specially valuable, as in answer to certain criticisms by Prof Vines<sup>1</sup> many doubtful points are explained. Specially to be noted is the clear re-statement of Weismann's contention that the nuclear substance is the sole bearer of hereditary tendencies, and the new evidence for it contained in the researches of Boveri and O. Hertwig. Equally noteworthy is the admission, in

<sup>1</sup> NATURE, October 24, 1890.

reply to Prof Vines' citation of the parthenogenetic fungi, that not only sexual forms may vary into new species.

It is to the last essay, that on "Amphimixis, or the essential Meaning of Conjugation and Sexual Reproduction," that most attention will be directed. Here there is a full statement, with important additions and alterations of the central part of Dr Weismann's theories. However they may bulk in public imagining, questions of acquired characters, of retrogressive metamorphosis, and so forth, are side issues of a search for the morphological expression of the processes of variation.

Originally Weismann explained the two successive divisions of the nucleus of an unfertilized egg which form the two polar bodies as, in the case of the first, an extrusion of that nuclear plasma which, having served to guide the maturation of the egg, became useless when the egg was mature, and in the case of the second, as a halving of the nuclear substance to make way for the incoming sperm-plasm.

In parthenogenetic ova, one division and only one was predicted and found. It was suggested that parallel processes occur in spermatogenesis.

Subsequent research by O Hertwig and others has brought to light these parallel processes, and Weismann, seeking for a sign, got rather more than he anticipated. For the processes in spermatogenesis show first a doubling of the germ-plasma, and then two successive reducing divisions, and it has been shown that exactly this happens in ova also. Accordingly, Weismann rejects his original explanation of the first polar body as an extrusion of ovo-genetic nucleoplasm, and the new problem comes to be, what is the cause of that doubling of the nucleoplasm which in primitive sperm and germ cells precedes the two reducing divisions?

Weismann supposes that the ancestral plasms or units of heredity, to which he gives the name "ids," are arranged in "idants," or nuclear rods. The doubling process takes place normally by longitudinal division, and simply doubles the number of idants without altering the arrangement of "ids." By this method the number of possible combinations is increased without alteration of the ids. The process is a mechanical one to increase the chances of combinations when the idants of sperm and germ cells meet. If the idants were coloured rods, to be arranged in pairs—say black, white, red, and yellow for four sperm idants, and orange, green, blue, and crimson for those of the egg-cell—obviously only four pairs are possible. The black would have to unite with one of the four others. But if before the arrangement in pairs each rod were split in two, there could be two combinations for black, and so on for the others. No doubt in many cases the number of idants is far greater than four, and the mechanical arrangement for variations correspondingly greater. From the large number of possible combinations there come the relative few individuals of the next generation, and there is thus a basis for the lawless and apparently capricious appearance of varieties. Next in importance comes Dr Weismann's belief, based on theoretical considerations, and supported by experiments on *Cypris*, conducted for seven years, that in parthenogenetic reproduction heritable variations may occur. But they are far less frequent than in sexual reproduction. But the whole of

this essay is full of intricate and curious speculation, speculation which will have to come before every student of biology, and which, whether much or little of it becomes incorporated in the body of accepted knowledge, will at least play a large part in guiding and stimulating present research.

#### ELEMENTARY CHEMISTRY

*The Standard Course of Elementary Chemistry* By E J Cox, FCS. Pp 344 (London: Edward Arnold.)

THIS book consists of five parts, which may be obtained separately or bound up in one volume. It is based upon the syllabus prescribed by the Education Department for teaching chemistry as a class or specific subject, and professes to lead the beginner from the "familiar" to the "less known" by means of "investigation," the teaching thus afforded being regarded as a branch of mental education as well as of useful knowledge. The five parts deal respectively with the properties of the common gases, the atmosphere, water, carbon and non-metallic elements, and with metallic bodies, combination, symbols and formulae.

The general plan of the book and the manner in which the subject is approached have a good deal to recommend them; the detailed treatment contains, however, much which could be improved, and unfortunately much which the learner will have to forget as he progresses in the study of his science. In the opening chapter, evidently for the sake of simplicity, the author uses the term heat in place of temperature. More confusion on the subject of heat is made later on by the use of equations, such as

which appears to attribute to heat a material existence, and even more unsatisfactory are bald statements to the effect that "no heat is produced in the formation of a mixture. Heat is produced in the formation of a chemical compound."

Considerable space is occupied in the comparison of the affinities of the elements. Because certain metallic oxides, including iron-oxide, are reduced when heated in a stream of hydrogen, the affinities of the metals for oxygen are said to be weaker than that of hydrogen for oxygen. In the case of iron and steam the author has to note that the inverse change—the oxidation of the metal by steam—readily occurs, and that the former statement as to the affinities of iron and hydrogen for oxygen, is apparently contradicted. This contradiction might have indicated the futility of attempting to compare affinities in a general way and not with reference to the special conditions under which the experiments were performed. The inverse change in the case of iron is said to occur when the "temperature" is favourable, but in reality the active masses of the reacting materials determine the direction of the change.

Inaccurate statements are numerous. Hydrogen is said to form "one-third part of water by volume," "a formula" is stated to "represent a molecule," and a base is given as "a compound of a metal with hydrogen and

oxygen" More objectionable still are occasional instances of bogus reasoning, the most striking example being an erroneous proof of the conservation of mass On three different occasions the indestructibility of matter is stated to be a consequence of the law of definite proportions Almost equally bewildering is an attempt to show that "a molecule occupies two volumes," an attempt which even when correctly carried out might well be excluded from a book which professes to discourage anything akin to cramming No advance is made in familiarizing the learner with accurate conceptions of atom and molecule, indeed the need for the latter conception in chemical philosophy is quite overlooked

Throughout the book the author's mode of expressing himself is frequently not the happiest To say that "air allows all bodies that will to take fire in it," or that "chlorine does not combine with an excess of hydrogen" is harmless enough perhaps On the other hand to talk of the "properties of a mixture" being the "sum of the properties of its constituents," or of the gas being kept dissolved in a bottle of soda water "by the pressure of the cork," or to say that "water has weight and exerts pressure" cannot but be puzzling to the intelligent reader

To prepare a thoroughly good introduction, of the most elementary kind, to the study of chemistry, is a work of considerable difficulty, indeed it is one which few of our leading chemists seem desirous of undertaking Enough we think has been quoted from the book under notice to show that the author has by far underrated the difficulty of this task

### LIFE AND DEATH

*Essai sur la Vie et la Mort* Par Armand Sabatier  
(Paris Babé et Cie)

PROF SABATIER'S "*Essai sur la Vie et la Mort*" forms the fourth volume of the "*Bibliothèque Évolutionniste*," a series of books published under the direction of M de Varigny, with the view of expounding in a strictly scientific manner the different principles and the diverse applications of the theory of Evolution The series most appropriately begins with a translation of Wallace's "*Darwinism*," and it is gratifying to our national pride to find that the two other works which have as yet appeared in the series, Ball's "*Treatise on Use and Disuse*," and Geddes' and Thomson's "*Evolution of Sex*," as well as the two others announced as in the press, are all by British authors

The present essay, which extends over 280 pp, is the outcome of a series of lectures delivered at the University of Montpellier It is written in a clear, simple style, devoid for the most part of all technicalities which appeal only to the specialist The problems of life and death are dealt with from an exclusively biological point of view, and questions of morality and theology are hardly touched upon It is difficult to do justice to the views expounded in the book in the short space at our disposal, but an attempt may be made to give a short account of its contents. The first part deals with life the properties of living matter are considered in great detail, and Prof Sabatier endeavours to show that the attributes of life are found to some extent, at any rate, in

dead matter According to his views "*la matière brute est vivante aussi*," but the manifestations are slow and dull To the Professor's mind living matter and dead matter are not absolutely distinct between the two states of matter there is only a difference of degree and not of kind "*La vie donc est partout, dans la matière dite inanimée comme dans la matière vivante*" The various features in which dead matter behaves like living, are considered at great length, but, curiously enough, no mention is made of Butschli's remarkable experiments on artificial amœbæ, recently described in the "*Quarterly Journal of Microscopical Science*."

This view being accepted, death in the ordinary sense of the word, naturally cannot exist, and the phenomenon which we usually call death becomes but another form of life—"la vie intense" simply passes into the state of "la vie lente" Immortality, according to our author, consists in the indefinite continuity of life ("la vie intense") without arrest or interruption. Like Weismann, he maintains that the negation or the contrary of such immortality involves the presence of a dead body or corpse. Weismann holds that ciliated infusoria are immortal if kept under favourable conditions, these conditions, of course, including frequent opportunities of conjugating Sabatier considers that such infusoria are only potentially immortal, and that the act of conjugation converts this potentiality into a real immortality In his opinion the primitive protoplasm was immortal, and the habit of dying has been acquired by the higher organisms in response to two stimuli, one internal and one outside themselves The internal cause of death is associated with a tendency innate in the living being to improve its position in the world, in response to which it has become more specialized, and developed new organs and powers This specialization has borne with it the seeds of death The external cause is the surrounding world, which constantly stimulates and promotes the organism to new efforts, and in the struggle for the mastery death is brought about

Although we fail to see that Prof Sabatier has thrown any new light upon the problems he attempts to solve, and although the explanations he advances seem to us inadequate, his book is a useful one, inasmuch as he gives us a careful summary of the numerous views advanced by various writers in the last twenty-five years, on the subject of life and death, and criticises with considerable ability the theories of Weismann, Goette, Minot, &c In fact, his destructive powers seem greater than his constructive.

A. E. S.

### OUR BOOK SHELF.

*Contagious Foot Rot in Sheep* By Prof G. T. Brown,  
C B, 16 pp, 8 illustrations, (John Murray)

THIS pamphlet is a reprint from the second part of the current volume of the Royal Agricultural Society's Journal A few additional remarks on the prevention of foot rot have been added, and if the instructions given were fully carried out, the disease would soon cease to be troublesome The preventive suggestions are (1) separation from the rest of the flock for one month of all animals newly purchased, and (2) isolation of all animals affected.

In discussing the treatment of the disease, Prof. Brown

insists upon the importance of detecting it at an early stage, and in the first part of the pamphlet he explains how to do this with certainty.

The pamphlet ought to be read by everyone interested in agriculture and to make it better known the Society has printed as a leaflet a few notes upon the subject. In America the pamphlet would be sent broadcast amongst those interested, and it is to be hoped that Government assistance may soon enable our own Agricultural Society to disseminate knowledge in a similar way.

W T

*How to Make Common Things* By John A Bower (Society for Promoting Christian Knowledge, 1892)

It would be a strange boy who never wanted "to make something." The present little book has been prepared for boys who feel this desire very strongly, but do not quite know how to set about the fulfilment of their wish. They will here find ample information on the best way of making a vast number of things, from a hat-rail to a galvanometer, from a pair of stilts to a needle telegraph. The author assumes throughout that those whom he addresses are not being taught by a personal instructor in handicrafts, and that they are not the possessors of an elaborate array of tools. His directions are clear and practical, and cannot fail to be appreciated by boys who find much to interest them in the exercise of ingenuity and manual skill.

*The Student's Manual of Deductive Logic, Theory and Practice* By K R Bose, (Calcutta S K Lahari and Co, 1892)

THIS book is intended for the use of students at the various Indian colleges, and will be regarded by most teachers of the subject as, upon the whole, a very good text-book. The author has read many of the best European writers on logic, and presents clearly a summary of their results. He begins with a definition of logic, gives some account of its "branches and parts," and then considers terms, propositions, and inferences. What he himself describes as "the distinguishing feature" of the book is a collection of problems and exercises with solutions, or hints towards solution, in close correspondence with the subject-matter of the text.

*A Text-Book of Agricultural Entomology* By Eleanor A Ormerod Second Edition (London Simpkin, Marshall and Co 1892)

THE first edition of this book was published about eight years ago. It consisted of lectures which the author had delivered at the Institute of Agriculture of South Kensington. There was not much demand for it until last year, when attention was directed to it by the arrangements of the County Councils for the promotion of agricultural education. The work was then so widely appreciated that a new edition was soon called for, and there can be no doubt that in its new form it will be more popular than ever, for Miss Ormerod has done everything in her power to make it not only scientifically accurate but practically useful. Students will find it of great service in helping them to a knowledge of insect life and of the best remedies for "infestations."

## LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

### A Functional Hermaphrodite Ascidian.

As of late years a considerable number of structural hermaphrodites have been shown to be protogynous or prot-

androus, or to have some special modification for the purpose of preventing self-fertilization, it may be of interest to have on record a case of a completely functional hermaphrodite.

I had living lately in one of my dishes a large *Ascidia* (probably *A. rubicunda* of Hancock) which I observed one morning to be expelling eggs from the apertures. The eggs were emitted in batches of from about twelve to twenty at a time, and immediately after each set of eggs came a little white milky jet which hung like a string in the water for a few seconds and then spread out and disappeared. On catching some of this string in a pipette and examining it with the microscope it was seen to be a mass of active spermatozoa. This alternating passage of ova and spermatozoa continued for fully an hour.

The ova at first floated at the surface of the water for a short time and then slowly sank to the bottom. On examining some of those on the bottom of the dish after a couple of hours they were found to have commenced development, being in various stages of segmentation, so there can be no doubt that self-fertilization had taken place.

Very likely this occurs in some other species also, but another common Ascidian (*Corella parallelogramma*), of which I had had several large specimens living a few weeks before, laid eggs in my dishes, and I could not detect any spermatozoa being produced by these individuals. They were functionally female although structurally hermaphrodite.

### The Present Comets

ON the 27th ult. about 15<sup>h</sup> G M T comet Brooks ( $\epsilon$ , 1892) had a tail 10' long, pointing at a position-angle of 280°.

At the latter part of last month Swift's comet ( $\alpha$ , 1892) was still a very conspicuous object in a 4 $\frac{1}{2}$  inch refractor. Observations on several nights showed that it not only still had a very faint tail—at position angle 260° on the 24th at 8<sup>h</sup>, when I observed it to be certainly 11' long, and suspected it to 21'—but that also there was an elongation nearly in the opposite direction, while I believe the radius of the head was less towards  $\alpha$  than towards  $\beta$ , but I have not been able to satisfy myself of this.

Sunderland, October 5

### Women and Musical Instruments

IN looking over a very large collection of musical instruments from the aborigines of America, I am surprised to find that there is not one peculiar to women, and that those of the men are never played by the women. It is true that the females beat time on various objects and may now and then use the rattle. This disappointing fact arrested my attention, and I am curious to know whether savage women, or any other women for that matter, have ever invented a musical instrument, and whether in savagery they even play upon those invented by the men. The composition and singing of songs might also be inquired into, though our American savage women do join in certain choruses.

### Determination of $g$ by Means of a Tuning Fork

MR C V BOYS informs me that for the converse process of determining the pitch of a tuning fork, the experiment I described recently is no new one, but has been used by him for the last ten years in the instruction of students in South Kensington. I observe, however, that he has not made the same use of the trace to eliminate the zero error.

A. M. WORTHINGTON

### THE TOTAL ECLIPSE OF THE SUN, 1893

AS I have been asked by some astronomers to give a description of the general appearance and climate of this part of Chile, in which a total eclipse of the sun occurs next year, I have drawn up for publication the following account—

The eclipse takes place on April 16, 1893, at about 8 15 A.M., Chile local time, and will be seen to the greatest advantage in this part of the Province of Atacama.

At the sea coast the central line of total eclipse passes close to Chañaral 29° S L. This is not the better known Chañaral, north of Caldera, but a small place equidistant from Coquimbo and Carrizal Bajo. The southern limit of total eclipse is 29° 50' S L just north of Coquimbo, and the northern limit 28° 10', just south of Carrizal Bajo.

The band of total phase stretches between these two limits in a north-easterly direction, across the country, from the coast towards the rising sun. Along the central line of this band the sun will be hidden by the moon for nearly three minutes. The eclipse will be total everywhere within the limits given above, but the total phase will be shorter and shorter the nearer those limits are approached, and outside of them the eclipse will be partial.

On the accompanying map of the Carrizal and Cerro Blanco and Copiapo Railway systems I have marked the northern and southern limits, and the central line of totality.

It will be seen that the port of Carrizal Bajo, 28° 4' S L, is just outside the total band, but the railway connecting it with Yerba Buena intersects the central line of total eclipse 70 miles inland, and a branch to Merceditas, 60 miles inland, at an altitude sufficiently high to be above the damp and hazy atmosphere of the coast. At the points of intersection the climate is simply perfect for astronomical observations, and is also, during the month of April, delightful to live in.

The accompanying form was filled up, in compliance

*Cloud Observations at "Mina Bronces," Chile, 1892*

Day	Local time			Remarks
	7 45 a.m.	8 15 a.m.	8 45 a.m.	
April 10	2	2	2	Clouds were light, allowing a slight shadow to be cast. Bright sun at intervals.
" 11	2	0	0	Clouds were on the horizon, so that the sun rose above them at 8 o'clock.
" 12	0	0	0	Perfectly clear sky.
" 13	0	0	0	Perfectly clear sky. Sun rose at 6 22 a.m.
" 14	0	0	0	Sun rose at 6 22 a.m.
" 15	0	0	0	Fresh wind. Sun rose at 6 23 a.m.
" 16	0	0	0	Sun rose at 6 24 a.m.
" 17	0	0	0	
" 18	0	0	0	Slight haze at sunrise. Sun rose at 6 25 a.m.
" 19	2	0	0	Bank of clouds near north-east horizon, which the sun rose above at 8 05.
" 20	0	0	0	Sun rose at 6 26 a.m.
" 21	0	0	0	" " 6 27 "
" 22	0	0	0	" " 6 28 "
" 23	0	0	0	" " 6 29 " Strong wind
" 24	0	0	0	" " " "
" 25	0	0	0	
" 26	0	0	0	
" 27	4	3	3	Haze thick at 8 13 a.m., but light at 8 45 a.m.
" 28	0	0	0	Sky got cloudy at midday.
" 29	0	0	0	
" 30	0	0	0	

KEY

- 0 = "Sun entirely clear from clouds"
- 1 = "Clouds generally scattered"
- 2 = "Clouds massed about the sun"
- 3 = "Sun in haze or fog"
- 4 = "Sun invisible in thick clouds"

NO 1198, VOL. 46]

with a request from Amherst College Observatory, to show the cloud conditions in the inland region during the month of April this year as an indication of what might be expected during the same month next year.

I had two series of observations made, one at Mina Bronces by Mr. Martin, chemist to the works (the results of which are hereto appended), the other at Cerro Blanco by Senor Miranda, at his mine. Both reports are in every respect alike. The 10th and 27th were cloudy, all the other days absolutely clear. As the two stations are some twenty-five miles apart, these reports show that there is no local weather, and that it is only when a general atmospheric disturbance, originating in the Cordillera de los Andes, occurs that the weather is affected at these high stations.

It will be seen that there was only one day—the 27th—out of twenty-one days of observation on which the sun was not visible at eight o'clock in the morning, for on the other cloudy day—the 10th—the sun was bright at intervals.

*Observatory Stations*

I have marked on the map, along the central line of totality, several stations that I think suitable for observatories, the positions are only approximately correct, for I have no means of determining them accurately, but the errors, if any, cannot be great.

Underlined are heights above sea level of some places shown on the map—

Yerba Buena railway terminus	3867 feet
Cerro Blanco, north hill	10,000 "
" south, Peineta	8000 "
Carrizo, in the valley, a small farm	5000 "
Merceditas railway station	2900 "
Cerro del Jote	6000 "
Cerro del Cobre	8000 "
Lay observatory	4000 "

*Cerro de Peineta* is part of Cerro Blanco, this Cerro Blanco is not part of the Andes, but a detached hill with low ground all round, and a clear view to the north-east. It is easily ascended by pack-mules.

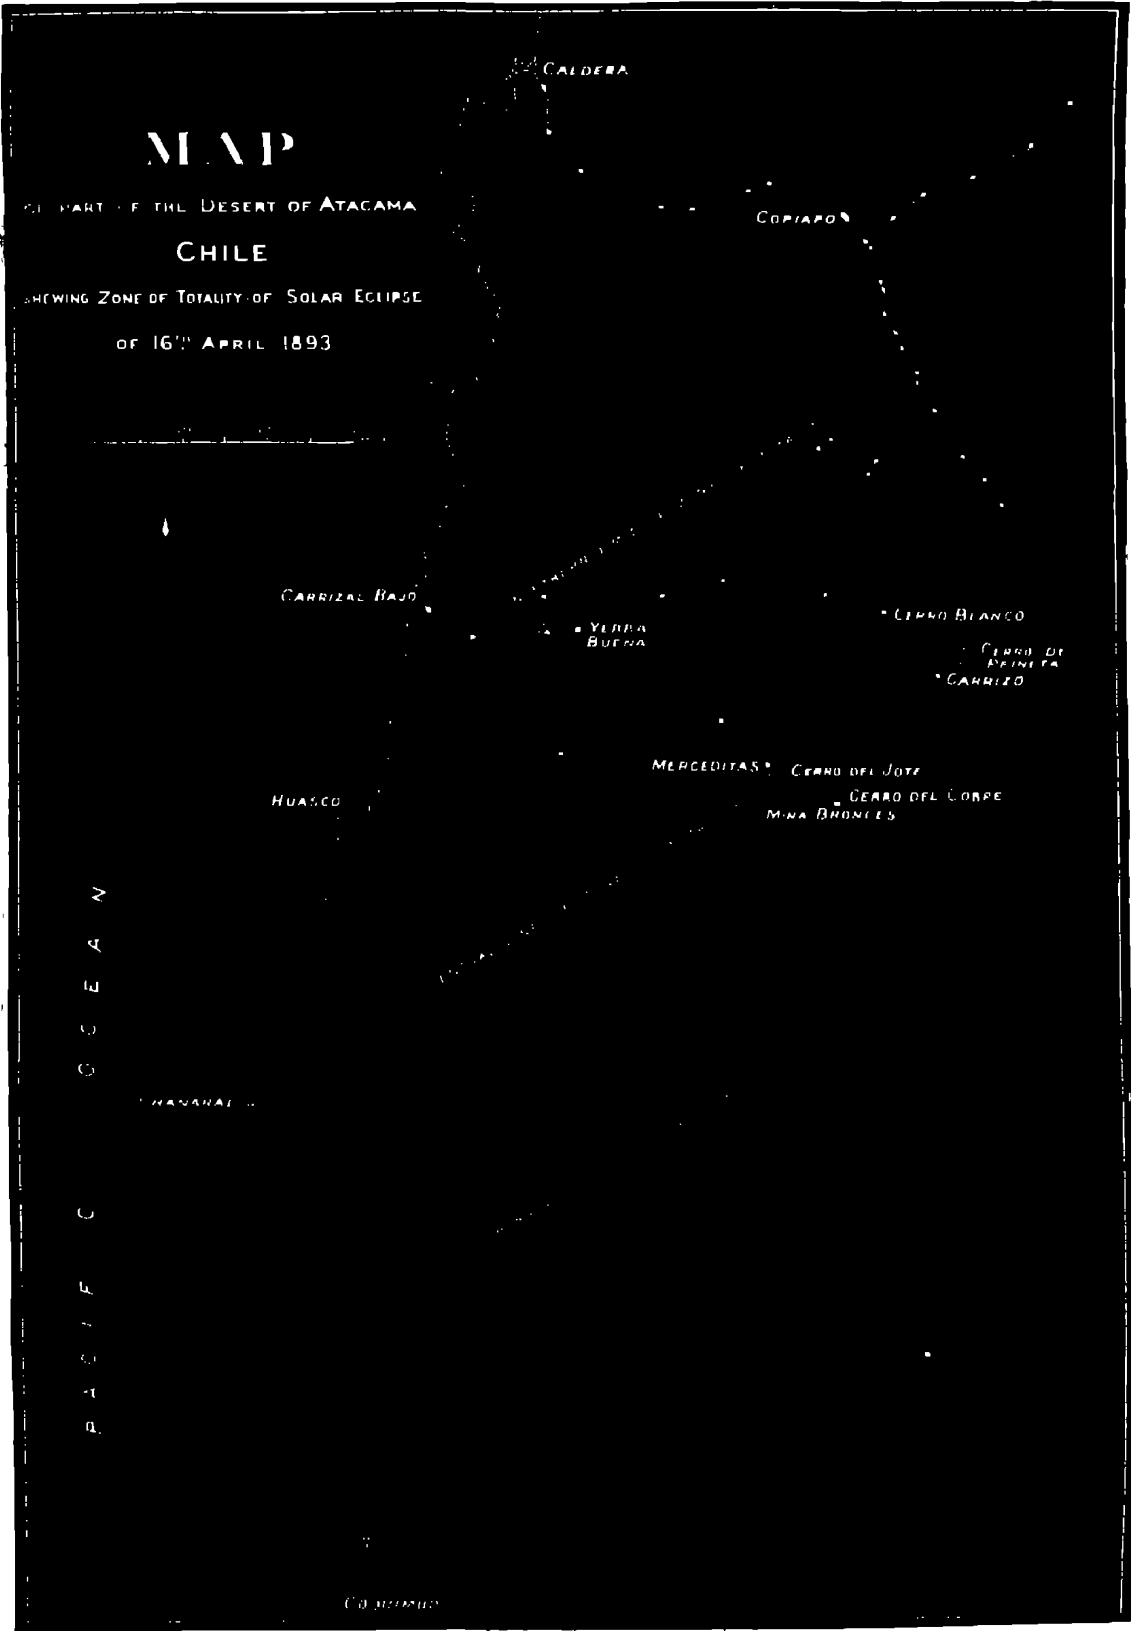

*Carrizo* is not a hill, but a small farm or large garden, irrigated by a mountain stream. The advantages of this station are nearness to the railway, a good road, and plenty of small hills of easy ascent to select from.

*Cerro del Cobre* is a good hill, but probably too far south. However, there are hills all the way from Merceditas that might be selected (see Mr. Martin's letter).

*Cerro del Jote*, near Merceditas, is accessible to pack-mules half-way up, higher than which it would not be necessary to go. Moreover, it is said that the rest of the ascent is difficult. The three hills, Cerro de Peineta, Cerro del Cobre, and Cerro del Jote, can all be seen from one another.

*Lay Observatory.* On April 15 I went to Merceditas and stayed overnight, as I wished to find near the railway station a hill on which the sun shone at an early hour on the morning of the 16th, through some opening among the surrounding hills, and which would be suitable for ordinary lay observers who had no expensive apparatus, but who wished to see the eclipse well through a smoked or coloured glass. To the south of the railway station I found a range of hills eminently suited to the purpose; at a height of 4000 feet above the sea the sun shone over a dent in the Jote at 6 40 a.m. The hill is much higher than 4000 feet, but I did not go higher. This is an excellent, well-sheltered spot, and would do well as a station for professional astronomers. I went up on horseback in forty minutes, but the ascent, from the railway station, could be easily made on foot in an hour. As I could not find any local name for this hill, I called it the Lay Observatory.

*Climate.*—At two o'clock in the afternoon of April 15

the temperature at Merceditas was 78° F, this was the hottest time of the day, and it was a warmer day than usual, and at 8 p.m. the temperature was 62° F. Next morning, the 16th, I got up at two o'clock to see the comet then visible, and found the temperature was 58°, at 5 a.m. it was 56°.

Everywhere on the coast of Chile, north of Coquimbo, the sun, in the morning, is almost always obscured by a thick haze which makes the sky of a dull lead colour. This haze is sometimes driven away by the sun during the forenoon, but just as often it remains all day, especially during the months of March, April, and May.

This hazy morning atmosphere extends inland for a distance of about 40 miles and up to an elevation above the sea of about 2500 feet, beyond this distance and height the sky is almost always clear and the air dry. Standing, in the early morning, on a mountain of 3000 to 4000 feet, or higher, you look down on a great white sea of mist covered with whiter ridges like motionless waves, and studded here and there with islands, which are the mountain tops piercing through. This haze is usually gone by nine o'clock, except within about five miles of the sea.

*Accommodation on the Hills*—Tents can be quickly and cheaply made with "esteros de totora," that is mats made of reeds. All the more temporary houses of miners and prospectors and of railway track repairers are made of these mats, which are seven feet square, and may be rolled up and carried from place to place. They form an article of commerce, and cost eighteen-pence each, or from eighty to ninety cents of Chile paper currency. During all the month of April and part of May it is quite safe to trust to this kind of tent, but not later than the middle of May, for rain or snow sometimes falls in the end of that month.

There are no venomous reptiles in Chile, nor are there mosquitoes on these hills, and fleas cannot live at an altitude of 4000 feet—no slight advantage.

*Rain*—On the Chilean side of the Andes, in the province of Atacama, rain generally falls twice in the year: the first rain is expected in June, the next in July, each rain usually lasting two days, and always accompanied with wind from the north. As soon as the wind changes to its prevailing quarter, the south, there is beautifully clear but cold weather. From two to three inches of rain fall in the year, but sometimes less than one inch. On Cerro Blanco it usually freezes every night from July till the end of August, and some snow lies on the mountain till September. On the hillsides there are plenty of bushes and small trees for firewood, and excellent water is found in all the higher valleys.

I have heard one objection to this district for observing the eclipse, which is, that as the eclipse takes place in the morning, and the sun is not high in the sky, it would be better to go farther east. This objection has no weight, on account of the extreme dryness of the atmosphere. At the mines on Cerro Blanco and the other hills everything gets dried up, Huasco raisins grow hard and rattle on one's plate like nuts, agricultural produce, such as wheat, beans, and barley, brought from Southern Chile as food for man and beast at the mines, loses two per cent of its weight every month for several months, office ink bottles have to be kept tightly corked or the ink very soon dries up, chairs and tables fall to pieces, veneer peels off, and a piano soon loses its tone. The sky is dark blue, and the sun rises white and dazzling without a trace of any other colour. The hills, the rocks, and the bushes cast dark shadows, and even every pebble the size of a hazel nut casts its shadow, so that in the early morning the gravelly ground seems half wetted with a shower, one side of every pebble is in bright light, the opposite in deep shadow.

Although the eclipse would be the object of greatest

interest to visitors, a few weeks might be profitably spent among the copper mines, and if any one wished to become a mine owner, plenty of mines are to be had for the asking. All the mines belong to the State. You have only to take up a mine, pay a nominal licence to the Government annually, and the mine is yours as long as you pay the licence. There are no royalties, no surface rents, and no export duties. The next thing to do is to make the mine pay, and this is sometimes done.

There is no sport in April, but after snow falls on the Cordillera, huanacos and immense flights of turtle-doves come down to feed on the lower slopes. Life, however, is never wanting. The region from Cerro Blanco southward as far as Coquimbo is the home of the fur chinchilla. It feeds on the nut of the carbon tree, *Cordia decandra* (Hook et Arn.), and on the pea of the algarrobbillo, *Balsamocarpum brevifolium* (Clos). This bush, which produces the tannin pod of commerce, thrives best far inland, on sunny, almost rainless slopes, but it must have one shower in June or July, otherwise it bears no fruit. If there be no rain for three or four years—as sometimes happens—the bushes do not die—they just wait. The same thing happens with all the other bushes, sometimes, for several successive years, they are without leaves, and though the soil seems as dry as dust, whenever rain comes they show themselves full of life.

British astronomers—professional and amateur—ought not to lose the opportunity of observing under such favourable circumstances this great eclipse. I doubt if better conditions were ever offered before. The distance to come is long, but the expense is not very great, and can be exactly counted beforehand. An expedition might leave Liverpool in February, by Straits of Magellan steamer, and be home again in June. Or, after the eclipse, go by steamer to San Francisco or Vancouver, and thence by rail to the World's Fair at Chicago, and instead of encountering hardship and danger in some unhealthy climate, have a pleasant trip all the way.

Though horses and mules can be got here, every one should bring a saddle and bridle.

In conclusion I would impress on the members of every expedition that may come out, the importance of selecting, as observing stations, places at a distance of at least 60 or 70 miles from the sea. On the other hand, the advantages of going farther inland are doubtful, and as the railways go no farther, travelling would be more difficult.

JOHN KING,

British Vice-Consul, Carrizal Bajo, and Engineer  
of the Carrizal and Cerro Blanco Railway

Carrizal Bajo, Province of Atacama, Chile,  
May 1892

(COPY OF MR. MARTIN'S LETTER)

*Mina Bronces, Jarilla, May 2, 1892*

DEAR SIR,—I have now the pleasure of enclosing the form which you sent to be filled up. As I did not receive your letter till April 9, I could not of course fill in the first nine days, but as you will see by the observations that as the last twenty days have been almost invariably clear, I think the astronomers could safely decide to come here as far as clearness of sky is concerned.

An observatory could very easily be placed on one of the spurs of the Cerro del Cobre, to the south of the latter. It is easily accessible to mules with 250 pounds and affords an unimpeded view of the sunrise.

Hoping that the filling up of the form will be found to fulfil all requirements. I remain, dear sir,

Yours sincerely,  
(Signed) WILLIAM M. MARTIN.

John King, Esq., Carrizal Bajo.

# DR MODIGLIANI'S RECENT EXPLORATIONS IN CENTRAL SUMATRA AND ENGANO

LITTLE more than two years ago, writing in this journal on the results of Dr Elio Modigliani's accurate and highly interesting exploration of Nias (NATURE, vol. xli p. 587), I made the remark that our young traveller had shown that he was made of the stuff of the very best of scientific explorers. It is therefore with no small pleasure and pardonable satisfaction that I now have the good fortune to show further proofs that I was not mistaken in thus judging him.

Those who have once tasted the sweets of true exploration in little-known lands, and who are animated by the smallest spark of *fuoco sacro*, have felt and know well that thirst for further travels which goads the late traveller to new wanderings. It was thus with my friend Modigliani, and he had hardly finished seeing his book on Nias through the press, when he began to long to be away again. He first thought of taking off the edge of his peregrinatory desire with a visit and collecting tour to the less-known parts of our new "Eritrea," but an accident, which might have had serious consequences, kept him back on the eve of departure. On regaining his health, far from being discouraged, he matured a wider and bolder plan—that of returning to the vast and lovely lands of the Malaysians, and penetrating to the heart of Sumatra through the country of the Toba Battaks.

Dr Modigliani left Florence in August 1890. Early in October he was at Siboga, then at Padang Sidempuan, in Sumatra, where he interviewed Mr van Hasselt, well known in connection with the big Midden Sumatra exploration, however, as the sequel proved, not much information and aid were got from Mr van Hasselt and his Government, besides, war was going on in the Toba region, but this did not deter Modigliani from his object. He had secured the services of Abdul Kerim, the Persian collector and taxidermist, who had been with Marquis G. Doria from 1862 to 1874, first in Persia, then in Borneo and Tunis, and finally at the Museo Civico at Genoa, which, under Doria's energetic and enlightened direction, has, during the last twenty-five years, been one of the most active and fertile centres of zoological research in the world. This was fortunate, for the Javanese hunters and collectors engaged at Buitenzorg were not very efficient.

Although he included in his baggage only things that were strictly necessary, he had to engage at Siboga forty-one carriers, mostly Toba Battaks, to convey it to the lake. That route, hardly practicable twenty years ago, is now safe, and the only trouble met with was from Dutch convicts engaged in repairing the road. It was on this road, at Ayer Kotti, that the American missionaries, Messrs Munson and Lyman, not many years ago, were killed and eaten by the Battaks of the neighbouring village, Huta Sakkak. The country rises continually from the coast until the highlands of the Toba plateau are reached, it is undulated with mountains and broad valleys, such as that of

Silindung, but on the highlands the forests have disappeared, and the watered depressions with dense vegetation and the clumps of bamboos surrounding the villages are dotted about. At Tarutung, the principal village of Silindung, Modigliani obtained important information on the independent Battaks from Mr Welsink, the Dutch Assistant-Resident, who had long resided in the Battak country, and been some time *Controleur* at Laguboti on Lake Toba, now occupied by the Dutch. The Singi Manga Rajah, head chief and religious primate of the Battaks, who had already given so much trouble to the Dutch, was again coming to the front, and this time in connection with the irrepressible Atchinese from the north—an alliance of hereditary foes, for the Battaks have always repulsed the Mohammedan Malays against the invading whites.

By the middle of October 1890, Modigliani was at Balige on the shore of Lake Toba, and on the edge of the wild and unexplored Battak country, the land of his dreams. He describes the lake as grand and imposing, but more like a northern lake, such as Loch Lomond, because of its bleak bare mountains and early mists, than what might have been expected in the heart of a tropical island. Lake Toba is about forty-four geographical miles

FIG. 1.—*Solu* (boat) on Lake Toba

in length, a large mountainous peninsula divides it in two—Tao Silalake on the north, and Tao Balige on the south. At Balige Modigliani had the use of a good house, once occupied by Mr Welsink. He paid an early visit to the *Controleur*, Mr van Dijk, at Laguboti, who placed at his disposal the Government boat with its crew, but requested to be informed of any excursion on the lake beforehand, as some of the lacustrine villages were hostile. Modigliani started for a first exploration of Lake Toba on October 27. An old chieftain, Ompu Rajah Doli, went with him, partly as guide, partly as protector. He was on his *solu*, the long swift canoe, excavated from a single tree, with which the piratical enterprises on the lake are so deftly performed, this, not one of the largest, was 18 metres long and 1 metre in width, it was manned by eighteen paddlers and one steersman. The place of honour is at the prow, which is singularly ornamented. At Ade Ade, one of the further villages, he secured the good will of the powerful chief, Ompu Rajah Hutsa, and with him visited

the site of Lumban Rajah, the former residence of the Singa Manga Rajah, destroyed by the Dutch. The chiefs and head men of several neighbouring villages had assembled, and many were the questions they put to Modigliani. Amongst others, they asked him who was his Rajah. "The Rajah Roma" said he. This caused a great discussion, after which one of the chiefs said: "How is it that we, having sent to Rajah Rom (not Roma) presents of horses and buffaloes, have never received a return or an answer?" Modigliani was at first rather embarrassed at so direct a question, but replied that the presents had not been received, having perhaps been intercepted. This appeared to convince them, and a Rajah Uti was mentioned as apparently the guilty party. I have mentioned this episode because it turned out to be a most fortunate

FIG. 2.—The guru Samalain

one for our traveller, who got to be known as the envoy of Rajah Rom, and even as that mystic personage himself. It appears that by that name a venerated authority is known to the Battaks, and Modigliani thinks it may be no less a personage than the Hindu god Rama. As the sequel will show, under the patronage of Rajah Rom, Modigliani was able to penetrate into the heart of the independent Battak country, where, in all probability, no other European would have been able to go; and many were the things he had to promise in Rajah Rom's name, and many the presents and great the aid he got as his envoy. The greatest depth found by Modigliani in Lake Toba was 450 metres, the temperature of the water was  $24^{\circ}$  to  $23^{\circ}$  C. at the surface, and  $23^{\circ}$  to  $22^{\circ}$  C. near the bottom. Only four species of fish, two of molluscs and two of crustaceans, appear to live in the lake.

As a locality better suited for zoological collections, Modigliani went in November to live in the forest of Si Rambe, where, at an elevation of about 1370 metres, he built himself a log hut. Here the maximum day temperature ranged from  $28^{\circ}$  to  $30^{\circ}$  C., the minimum night temperature from  $12^{\circ}$  to  $13^{\circ}$  C.

It was from his hermitage in Si Rambe that Modigliani, eluding the official impedimenta, started on his adventurous and bold journey across Sumatra, right through the country of the independent and hostile Battaks. Now his supposed connection with the legendary Rajah Rom did him a right good turn, for the yet more or less independent chiefs sought him out, hoping that through his influence Rajah Rom might be induced to redress their wrongs. Amongst these was a *guru*, one of their priests, wise men, and *literati*, named Samalain, a staunch friend of the Singa Manga Rajah, who not only visited Modigliani but undertook to guide and protect him in his exploration of the (by Europeans) untrodden Battak territory. In one of his letters to Marquis Doria, Modigliani gives a vivid description of the savage energy of *guru* Samalain, of his devotion to the Singa Manga Rajah, and of his love of independence. The *guru* sent seven of his devoted followers to act as carriers, and taking one of his Javanese hunters and his interpreter, Si-gu-tala, a Battak, Modigliani left his encampment in the forest of Si Rambe at midnight on December 19, 1890. The utmost caution was necessary to cross the frontier line without being discovered by the colonial authorities. After a forced march of ten hours, the *guru* having joined him on the way, Modigliani reached the village of Lumban Bulu, well within the territory of the independent Battaks. The village chiefs, with armed retainers, and those of some neighbouring villages, all fully armed and equipped, with spears, flint-lock muskets plated with silver and ornamented with ribbons, and their peculiar swords with heavy ivory handles, accompanied and surrounded him. His reception was far from friendly. They would not believe that he was not a Dutch emissary, and spoke of sending him back, even the energetic protestations of the *guru* Samalain were received with signs of doubt. At this juncture our traveller had a happy thought, and drawing from a pocket the flag of Italy, he suddenly displayed it, exclaiming: "This is the flag my Rajah gave me, see, it is different from that of the Dutch, but when it is unfurled Debata (God) is present—you must rise and uncover your heads." The difference was at once noted, and Puttua, the chief who had shown himself most hostile, turned to Modigliani and said, "*Tabi, rajahnami*" ("Hail, my chief"). The others joined, and then two fowls and a pipe were brought to our traveller, and orders given to prepare the *sarak* of welcome and friendship. This is done with special ingredients, the absence of any of which would do away with the sincerity of the offering.

Modigliani was thus allowed to enter the independent Battak country. The next day he resumed his journey towards the east coast. He had to pay for passing a bridge. The Battaks know well the value of money, and use the Spanish dollar divided into 480 *dots* of copper, bearing the date 1804, the British arms, and the inscription "Island of Sumatra" (or the same inscription in Arabic), or else simply a fowl.

Amongst the many interesting things he saw, heard, and learnt, special mention must be made of the magnificent waterfall formed by the emissary of Lake Toba. Modigliani had some difficulty in visiting it, for it is the reputed abode of powerful spirits, or *sombaon*. It is, he says, grand beyond description, all the rivers of the region join the emissary of the lake in the fall, the native name of which is Martua Sapuran Si-arimo: the result is the River Assahan, which flows into the Eastern Sea near Tangion Balei. This is an important geographical discovery, and our friend may well be proud of it. He succeeded in taking a magnificent photographic view of

the principal cascade. Two Battak villages, Tanga and Suanan, are on each side of the fall. Modigliani managed to visit both, though hostile to each other, as he learnt, on account of cannibal feats recently committed reciprocally; thus cannibalism is not yet extinct amongst the Battaks. In this trip Modigliani went as far as Bandar Pulo, near the east coast, but not wishing to get into difficulties with the *Controleur* at Tangiong Baler, he turned back towards Toba, taking this time a new route up the valley of the Qualu or Kuwalu River.

The return journey was adventurous, and more than once Modigliani and his small party were in imminent danger. A war expedition of the Dutch had recently been this way, and the depredations and looting of the so-called friendly chiefs and their followers had left behind visible traces, and a burning sense of hate and vengeance against the *soldado* of the Cumponi (Dutch), although nothing can be said against the conduct of the Dutch colonial troops. It required all the energetic persuasions of *guru* Sumalain and all the calm courage of Modigliani to avoid hostilities. At the village of Si Buttua, well fortified and in a commanding position, as most are, admittance was gained with difficulty, and matters went worse at the village of Lumban Ballic, where, however, finally Modigliani, as Rajah Rom, was treated with high honours and a dance. His last station was at Hite Tano, the native village of his man Si-gu-tala. Here, after some delay and hesitation, he was treated with friendliness, and to celebrate the return of Si-gu-tala a buffalo was killed, a very grand feast in the Battak country. A good tramp of fourteen hours took Modigliani from Hite Tano back to his log hut in the forest of Si Rambe. He had been away a little more than a month.

Of course, this adventurous trip of Modigliani amongst the independent Battaks got known, the Dutch authorities informed him that he would be expelled if he attempted again to cross into the Battak country, and he found that all his movements were watched and reported by the native police (*opas*). He therefore decided to return to Siboga, where he was on March 14, 1891. He remained there collecting and taking notes until the first days of April, when he proceeded to Bencoolen.

The Geographical Society of Batavia had invited him to explore the island of Engano, and a Government steamer was to convey him there. Modigliani had accepted with delight; but, after waiting some time in vain at Bencoolen for the promised steamer, he decided to start on his own account, and did so, engaging the *prahu* of a Chinaman.

Engano, the furthestmost of the interesting islands which guard the western coast of Sumatra, has up to the present date been all but a *terra incognita*. Crawford, in his admirable "Dictionary of the Indian Archipelago," gives scant and partly erroneous information on Engano; whilst Vivien de St. Martin, generally so accurate, in his great

"Geographical Dictionary," now being issued, says very little, and tells us that the natives are Negritos! And yet Rosenberg visited and explored the island not many years ago. Modigliani, during his stay of over two months, made a thorough exploration of Engano, and of the ways and customs of its natives, and it is indeed fortunate that he went there and gathered such rich ethnological and anthropological materials, for the natives of Engano are rapidly dying out, like those of other savage islands. Ten years ago they were about 8000, now, by the last reckoning of the Dutch Agent, they are reduced to 840!

The natives of this island certainly belong to the great

FIG. 3.—Battak chief and his wife

Malayan family. On looking over the photographic portraits taken by Dr. Modigliani, I was forcibly reminded of the Nicobarese, and Modigliani agreed with me on examining the fine series of photographs of natives of the Nicobar Islands in my collection, which I owe to the kindness of my friend, Mr. E. H. Man, Deputy Commissioner of the Andaman and Nicobar Islands, and well known for his exhaustive anthropological researches in those two interesting groups.

Modigliani remained in Engano from April 25 to July 13, 1891. His health, which had hitherto resisted many

and various sore trials, was at last injured by the pestilential miasmatic emanations of the mangrove swamps of Engano, and he came away just in time to save his life. At the end of July he embarked at Batavia, and by the end of August we had the pleasure of welcoming him back to Florence.

He has already given brief accounts of his exploration of the Toba country in letters and in two lectures recently delivered at Rome and Florence. He is now busy working out his ethnological materials, those pertaining to zoology have already been partly examined by specialists. The principal novelties in zoology are, as was to be expected, from Engano. Amongst those already published I recall the following—Birds *Graculus enganensis*, *Pericrocotus modiglianii*, *Zosterops imerta*, *Geococcyx lucicola*, *Calornis enganensis*, *Gracula enganensis*, *Corophaga aethiops*, and *Macropygia cinnamomea*, are new species from Engano, recently described by Count Salvadori, besides, Modigliani has established the hitherto unknown habitat of a lovely Parroquet (*Palaornis modesta*). Reptiles *Draco modiglianii*, *Lycosoma relicum*, and *Coluber enganensis* are new species recently described by Dr Vinciguerra, also from Engano.

On the anthropological and ethnological materials collected by Dr Modigliani on this voyage, which are many and of great interest, I intend writing a special report, which will be published elsewhere. I will therefore, in concluding this communication, merely draw attention to their scientific value, mentioning the more important series.

Amongst the Toba Battaks, Modigliani was not successful in obtaining human skulls, but, with the help of *guru* Samalain, he was able to take with rare ability and perfection a magnificent series of plaster masks of the face from life, both of men and women. He has made, besides, a splendid collection of photographs illustrating the people and their habits. A most extensive and perfect series of actual specimens and carefully constructed models made on the spot illustrate completely the houses, *ropos*, and boats, with their ornaments, the agricultural implements, house furniture, dress and personal ornaments, food and stimulants, with the utensils pertaining thereto, work-tools, and weapons offensive and defensive, religion and superstitions, witchcraft and literature. The carvings on the houses, and the patterns of the textile fabrics of the Toba Battaks, are indeed remarkable as specimens of the finest style of ornamentation. Amongst the numerous series illustrating the crude religion and manifold superstitions of this singular people, I may mention the carved wooden figures, with movable arms and a square hole in the chest, in which is the sacred relic (*pangulubalang*) or talisman containing part of the remains of a sacrificed child, these figures, of which Modigliani has collected quite a number, are as rudely made as the *kurwars* of North-west New Guinea. Of the remarkable magic staffs, called generically *tungal paghaluan*, but which appear to have individual names, Modigliani has secured seven, they consist of superposed figures, more or less conventionalized, but beautifully carved in a hard dark wood in most cases, in which the human figure and those of the elephant, buffalo, lizard, and serpent are variously entwined. Modigliani thinks that each of these staffs symbolizes the history of the village or clan to which it belongs, in which case they might be compared to the genealogical Maori staffs, like the one recording the history of the Ngatirangi tribe, now in the British Museum. As samples of the little-known literature of the Battaks, Modigliani was fortunate enough to secure twenty of their books, now rare. They are ancient-looking tomes of various sizes, bound in wooden boards, the leaves are of beaten bark, the writing minute, mystic figures (*adika*) being occasionally intercalated. These books, written by learned *gurus*, are of a sacred, medicinal,

and encyclopædic nature, and much very valuable information on the Battaks will certainly be gained by their translation.

At Engano, Modigliani was able to obtain three skulls, and took six excellent plaster casts from the living. His series of photographs is also fine, but unfortunately some of the best were spoiled by the heat. I have already noted the remarkable resemblance which the natives of Engano show with those of the Nicobar Islands. There are amongst them faces which also recall Polynesian and especially Micronesian types. Thus the photographs taken by my friend, over a hundred,

FIG. 4.—Battak gentleman

are of great ethnological value. The collections illustrating the ethnography of the Engano islanders are, I should say, complete besides beautiful models of the singular houses and canoes, and actual specimens of the ornamented portions, viz doors, cross seats, &c, the mourning and ceremonial dresses and ornaments, house utensils, weapons, &c, are represented by a great number of carefully selected specimens.

In conclusion, I can only say that Dr Modigliani has done much excellent work, and that we may look forward with pleasure to the publication of the results of his investigations, both in zoology and in anthropology.

HENRY H. GIGLIOLI

#### A MODERN REVIVAL OF PROUTS HYPOTHESIS<sup>1</sup>

IT frequently happens in the history of science that the line of thought engendered by one branch of study proves applicable in a totally distinct field. In accordance with this principle a great stimulus is occasionally given in some particular line of research by the encroach-

<sup>1</sup> "On the Origin of Elementary Substances and on some New Relations of their Atomic Weights." By Henry Wilde, F.R.S. (London: Kegan Paul, Trench, Trübner, and Co., 1892.)

ment of an investigator who brings the vitalizing ideas derived from his own work to bear upon a new subject. It was with some such notions as these that we were predisposed to welcome Mr. Wilde's attempt to deal with the greatest of all the problems presented by modern chemistry, but a careful consideration of the author's views has, we regret to say, left us in a state of disappointment for reasons which we will endeavour to explain to the readers of NATURE.

The work under consideration is a quarto pamphlet of eighteen pages and a folding table giving the author's and other arrangements of the chemical elements. It consists of a preface dated May 1892, and a paper reprinted with additional notes from the Memoirs of the Manchester Literary and Philosophical Society for 1883 and 1887, the results having been first made known in the Proceedings of the same Society for April, 1878. The preface and paper are followed by translations of the same into French. Everything emanating from a recognized authority in a distinct department of science is worthy of consideration by chemists, and there are scattered throughout the work many statements which we cannot but endorse. There are, moreover, a few suggestions here and there which might be fruitful, and although the general result is disappointing, it is opportune that the author should have restated his hypothesis at a time when all chemists have more or less assimilated the views of Newlands, Mendeléef, Lothar Meyer, and their followers. It may be stated at the outset that Mr. Wilde's theory has nothing to do with an electrical origin of the elements as his reputation as an electrician might at first lead us to imagine.

In very brief terms the author's theory is that the elements have been evolved from hydrogen by a process of nebular condensation. In so far as he regards the elements as polymerides (as we might now express it) of hydrogen, there is nothing new in the idea. It is Prout's hypothesis pure and simple. We are far from asserting that this hypothesis has been disproved, there is a fascinating simplicity about it—it is so much in harmony with the general course of nature that matter should have been evolved from some primordial stuff that we should like it to be true, but unfortunately the most exact determinations of atomic weights have in later times not always conformed to the requirements of the hypothesis. Mr. Wilde in effect, if not in words, says *tant pis pour les faits*. These numbers ought to be whole multiples of the atomic weight of hydrogen, and Mr. Wilde unhesitatingly makes them so. In some cases the discrepancy between the observed atomic weights and those calculated from the theory is so great—apart from the doubling or other manipulation of some of the old numbers—that this alone will damage his case in the eyes of those who know the scrupulous care taken and the variety of methods resorted to in order to secure purity of material in such determinations. We give a few examples—

	Accepted Atomic Weight	Calculated		Accepted Atomic Weight	Calculated
Cu	63.18	62	Cr	52.45	54
Be	9.08	8	W	183.6	186
Sc	43.97	42	Si	28.2	35
Ga	69.9	96	Ni	58.6	56
Y	88.9	123	Co	58.6	56
In	113.6	150	Ir	192.5	196
Ta	182	185	Os	191.12	196

A large number of atomic weights not given above differ by one unit from the experimental results, in fact, more than half the existing determinations are in the light of the present theory erroneous to a most humiliating extent.

We are not bigoted in our faith respecting the unsalable accuracy of the determinations of these constants; we all know the enormous difficulties which meet the chemist in his attempts to obtain his compounds in a state of purity. In one part of his paper the author sug-

gests "that slight differences in the determinations may arise from the latent affinity which some elements have for minute quantities of another," which is a reasonable supposition in its way, although not very happily expressed. But later he somewhat inconsistently remarks "that these discrepancies are due to some unknown cause which prevents their [i.e. Cu, Zn, &c.] true atomic weights from being ascertained."

From a purely philosophical standpoint the author's proposed emendations of the atomic weights are perfectly legitimate. If it can be satisfactorily proved that these constants are the numerical consequences of some general law requiring that the relative combining weights referred to hydrogen should be whole numbers, it is correct to conclude that our determinations are, through experimental error, difficulty of separation, &c., faulty. That some such law exists has been surmised again and again, but unfortunately the proof has not yet been found. Now the central idea of Mr. Wilde's paper is that there is an analogy between Bode's law of the planetary distances and the numerical relationships between the atomic weights, and he even attempts to show that this analogy is the result of a causal connection between the phenomena. This is the most important suggestion in the work, as the whole novelty centres in this idea, and the subsequent acceptance of his views will turn upon the strength of his case in demonstrating these two points: first, that Bode's "law" is the expression of a physical reality, and, secondly, that the numerical relations between the atomic weights are the physical expressions of a causal connection between the distances of the planets and the condensation of the primordial matter ('hydrogen').

The first point is purely astronomical, and we prefer to let astronomers speak on the subject. Prof. Simon Newcomb says ("Popular Astronomy")—

It is true that many ingenious people employ themselves from time to time in working out numerical relations between the distances of the planets, their innses, their times of rotation, and so on, and will probably continue to do so, because the number of such relations which can be made to come somewhere near to exact numbers is very great. This, however, does not indicate any law of nature. If we take forty or fifty numbers of any kind—say the years in which a few persons were born, their ages in years, months, and days at some particular event in their lives, the numbers of the houses in which they lived, and so on—we should find as many curious relations among the numbers as have ever been found among those of the planetary system.

The author thus gets but little support from astronomy and it is to be observed that in the list of planetary distances which he gives he stops short at Uranus, Neptune occupies an awkward position for Bode's "law." The flight which is taken in connecting this "law" with the atomic weights is, however, a bold one and worthy of being given in the author's own words. After stating the nebular hypothesis he says—

That this gaseous or primordial substance consisted of a chaotic mixture of the sixty-five elements known to chemists is a notion too absurd to be entertained by any one possessing the faculty of philosophic thinking, as the regular gradation of properties observable in certain series of elements clearly shows that elementary species are not eternal, but have a history, which it is the proper object of physical science to unfold.

With this we most cordially agree, and as the same idea has been repeatedly expressed by chemists and physicists, we do not imagine that it is likely to be controverted. Then he continues.—

One of the principal facts which, to my mind, establishes the nebular theory of the formation of planetary systems on a firm basis is Bode's empirical law of the distances of the members of the solar system from each other and from the central body, as in this law is comprehended the idea of nebular condensation in definite proportions. Now, if elementary species were created from a homogeneous substance possessing a

capacity for change in definite proportions, it is probable that the greater number of elements would be formed during or after the transition of the nebular matter from the annular to the spheroidal form. Moreover, as great cosmic transitions are not made *per saltum*, it might be expected that some modification of the law of nebular condensation into planetary systems, as exhibited in Bode's law, would be found on the further condensation of the primitive matter into elementary species.

There appears to be a flaw in this chain of reasoning which weakens the whole paragraph. It is difficult to see how a law, which the author himself describes as "empirical," can establish a theory on a "firm basis." We admit that an empirical law may be of use—Bode's law is a case in point—but surely it must pass beyond the stage of empiricism before it can establish anything on a firm basis. The astronomical foundation having therefore been shown to be insecure, or, in the opinion of astronomers, even non-existent, it remains next to consider the second point, with respect to which we shall let the author speak for himself—

One objection raised against the theory which I have propounded on the origin and compound nature of the elements I will remark upon, is an alleged want of causal connection between the series of planetary distances and a series of atomic weights. Now, considering that specific gravities and atomic weights are admittedly correlated properties of the elements, and that specific gravities are fundamentally correlated with the dimensional properties of space, it follows that planetary condensations within interplanetary space are correlated directly with atomic condensations and atomic weights within that space. Hence the law that every increase of atomic weight, in a well-defined odd or even series of elements, is attended by an increase of specific gravity, is a natural consequence of the theory.

This is quoted from the preface, the mechanism of the process is described in the paper as follows—

In the present hypothesis it is assumed—(1) That a mass of hydrogen, of a curvilinear form, acquired a motion of rotation about a central point, which caused it to take a spiral or convolute form. (2) As each successive spiral or convolution was formed, the particles of hydrogen combined with themselves, as far as the septenary combination, to constitute the type of each series of elements—the number of types or series being equal to the number of convolutions of the rotating gas. According to this view, the elementary groups may be represented as forms of  $H_n$ ,  $H_{2n}$ ,  $H_{3n}$ ,  $H_{4n}$ ,  $H_{5n}$ ,  $H_{6n}$ ,  $H_{7n}$ , the internal convolutions forming the highest type,  $H_{7n}$ , and the outer convolution the type  $H_n$ . (3) That on a further condensation of the elementary matter a transition from the spiral to the annular form occurred, during or after which the series under each type was generated in concentric zones and in the order of their atomic weights, until the highest member of each species was formed. (4) That as the elementary vapours begin to condense, or assume the liquid form, their regular stratification would be disturbed by eruptions of the imprisoned vapours from the interior of the rotating mass. The disturbance would be further augmented by the subsequent combination of the negative with the positive elements, and also by the various solubilities of their newly-formed compounds, so that the evidence of such stratification of the elementary vapours as I have indicated must necessarily be more fragmentary than that of the geological record.

In support of this last statement the author mentions the well-known association of allied elements in minerals.

The idea of an evolution of matter by a process of nebular condensation as above set forth is to be found under various forms in the writings of Herbert Spencer, of Sterry Hunt, Lockyer, and others. Also, it may be remarked in passing, that the hypothesis of stratification in the order of density was applied to the sun by Johnstone Stoney about the year 1867. In fact the general notion of elementary evolution is so obvious that it cannot fail to present itself again and again to those who think over such problems as are here dealt with. For the sake of chemical philosophy we only wish that this speculation could be placed on a firmer basis of observation or experiment—if for no other reason in order that the minds of

chemists might be cleared of this inorganic *Urschleim* in which since the time of Prout they have been compelled to wallow.

Reduced to its ultimate terms it will appear, then, that Mr Wilde's view is a combination of the nebular with Prout's hypothesis, the latter being stated with a precision and boldness which certainly goes beyond any utterance on this subject to be met with in chemical literature since the time of its promulgation. Although the author takes hydrogen as the first stage in his evolutionary series he admits, with Prout, that this element "may have been evolved from an ethereal substance of much greater tenuity." Under the seven stages of condensation comprised from  $H_n$  to  $H_{7n}$  the author arranges all the chemical elements in a tabular form leaving gaps for unknown elements, and correcting the atomic weights where necessary so as to make them accord with the hypothesis. Some of the results of this treatment have already been alluded to. The way in which Bode's method is applied will be understood by taking one example, viz the first series,  $H_n$ —

0	0	7	Li	7
1	23	0	Na	23
2	23	7	K	39
3	23	7	Cu	62
4	23	7	Rb	85
5	23	7	Ag	108
6	23	7	Cs	131
7	23	7		154
8	23	7		177
9	23	7	Hg	200

The rule of construction is multiply the atomic weight of the second member ( $Na = 23$  in the above) by the arithmetical series and subtract the atomic weight of the first member ( $Li = 7$  in the above) from the products, the results are the atomic weights of the elements of the series. This method is applied also to the group  $H_{2n}$  with tolerable success, *provided the atomic weights are modified to even numbers and that the atomic weight of beryllium is made 8*. Mr Wilde's second group is given below—

Be, 8, Mg, 24, Ca, 40, Zn, 64, Sr, 88, Cd, 112, Ba, 136, x, 160, x, 184, Pb, 208

This is presumably one of the new relations between the atomic weights referred to in the title of the paper. In the third group, however ( $H_{3n}$ ), very considerable modifications of the atomic weights have to be made, as will be seen from the author's results—

C, 12, Al, 27, Sc, 42\*, Ce, 69\*, Ga, 96\*, Y, 123\*, In, 150\*, Er, 177\*, Tl, 204, Th, 231

The six numbers marked with an asterisk stand for 44, 92 or 141, 70, 617 or 895, 756 or 1134, and 1706 respectively. A system which necessitates this amount of manipulation of experimental results will certainly fail to commend itself for adoption by chemists. The proposed change of beryllium from 9 to 8 is directly opposed by the determination of the vapour density of the chloride by Nilson and Pettersson, and if adopted would cause this element to become still more divergent from the law of Dulong and Petit. The vapour density of indium chloride as determined by Nilson and Pettersson is in accordance with the accepted atomic weight of that element and opposed to that given by Mr Wilde. The elements associated in the first and second groups respectively, may be allowed to pass as natural allies, but the separation of carbon from its analogues, silicon, titanium, &c., and its association in the third group with aluminium, scandium, gallium, &c., is a violation of known relationships. The four halogens according to their atomic weights belong to the author's first ( $H_n$ ) group. They are regarded as the negative analogues of the alkaline metals and are therefore placed in a separate column.

in such a way as to bring out the relation that there is a constant difference of 4 between each halogen and its positive analogue —

Na,  $23 - 4 = 19$ , F,  $39 - 4 = 35$ , Cl, Rb,  $85 - 4 = 81$   
Br, Cs,  $131 - 4 = 127$ , I

In a similar way the oxygen group is made into a negative column having positive analogues in the H<sub>2</sub>n group and showing a constant difference of 8 —

Mg,  $24 - 8 = 16$ , O; Ca,  $40 - 8 = 32$ , S, Sr,  $88 - 8 = 80$ ,  
Se, Ba,  $136 - 8 = 128$ , Ta

Of course chemists have long been familiar with various numerical relationships between groups of allied elements, but this does not appear as sufficient evidence for altering the atomic weights of Br, Cl and Se, unless these relationships can be conclusively shown to be the necessary result of a general law

But apart from such defects as have been pointed out, it will be seen that the proposed grouping breaks down altogether after the third group. The author is hardly fair when he says (Preface, p. iv) — "While the multiple relations subsisting among the atomic weights of the other series of elements are highly interesting, they do not possess, in the present state of our knowledge, that degree of precision which is the distinguishing feature of the series H<sub>n</sub> and H<sub>2</sub>n. An exception might, however, be made in favour of the series H<sub>3</sub>n, &c."

As a matter of fact it is not a question of "degree of precision" at all, for, as far as we can see, the other groups do not lend themselves to the Bodeian method, at any rate, not in the form applied to the groups H<sub>n</sub>, H<sub>2</sub>n, and H<sub>3</sub>n. We give the author's results as compared with those obtained by the application of his own method —

#### Group H<sub>4</sub>n.

$x = 16$ ,  $\alpha = 32$ ,  $\Gamma = 48$ ,  $\text{Ge} = 72$ ,  $\text{Zr} = 92$ ,  $\text{Sn} = 116$ ,  
 $\text{La} = 140$ ,  $\alpha = 164$ ,  $\text{U} = 188$ ,  $\text{U} = 240$

The numbers obtained by the rule ( $1, 2, 3, 4, \&c \times 32$ , and 16 subtracted from each product) are 32, 48, 80, 112, 144, 176, 208, 240, &c, which, after Titanium, do not represent any atomic weights in the group till Uranium is reached

#### Group H<sub>5</sub>n

B = 10, P = 30, V = 50, As = 75, Nb = 95, Sb = 120,  
 $x = 140$ ,  $x = 165$ , Ta = 185, Bi = 210

Calculated ( $1, 2, 3, 4, \&c \times 30$  and 10 subtracted from each product) the numbers are — 30, 50, 80, 110, 140, 170, &c

#### Group H<sub>6</sub>n

$x = 18$ ,  $x = 36$ , Cr = 54, Mo = 96,  $x = 144$ , W = 186

Calculated ( $1, 2, 3, 4, \&c \times 36$  and 18 subtracted from each product) the numbers are — 36, 54, 90, 126, 186, &c

#### Group H<sub>7</sub>n

N = 14; Si = 35; [Fe = 56, Mn = 56, Ni = 56, Co = 56],  
[Pd = 105, Rh = 105; Ru = 105, Os = 105], [Au = 196,  
Pt = 196, Ir = 196, Os = 196]

Calculated ( $1, 2, 3, 4, \&c \times 35$  and 14 subtracted from each product) the results are — 35, 56, 91, 126, 161, and 196

The association of nitrogen with silicon and the metals of the iron and platinum groups is, to say the least of it, incomprehensible. We have thought it desirable to give this analysis, for no reason is given in the paper for this particular grouping after the third series, beyond the well-known chemical relationships of the elements which, as we have seen, is sometimes violated in a most unaccountable way. The groups are obviously not constructed by the Bodeian method, the atomic weights are modified in many cases by one or two units, and the result is a classification which differs only from the received classification on points which cannot possibly be conceded by

chemists. The reason why silicon is separated from its analogues is as follows —

Now, if silicon were the true analogue of titanium, the oxides of these elements should be isomorphous, whereas the crystalline form of quartz is hexagonal, while rutile, anatase, brookite, zirconia, and tinstone (similar oxides of members of the series H<sub>4</sub>n) are tetragonal, consequently, silicon does not belong to the series H<sub>4</sub>n

This is a point, and out of justice to the author we give it for what it is worth,<sup>1</sup> but the atomic weight of silicon has been determined by the vapour density of its chloride, and the result is fatal to Mr Wilde's classification. His attempt to justify the atomic weight 35 by an appeal to the specific heat is unfortunate, because he takes the old determination by Regnault (0.176) instead of the more recent determination by Weber (0.203 at 230° C). Moreover, he is inconsistent in not allowing the same correction for boron and the other elements which deviate from Dulong and Petit's law

We cannot go much further into the details of this paper. Enough has been written to justify the disappointment which we expressed at the outset, and it is only the intrinsic importance of all questions bearing upon the origin of the elements that has warranted such extended treatment. It appears that the numerical relations which are brought out by the author's method have either long been known or else—as in his application of the Bodeian method—they do not exist beyond a limited number of groups. The results do not take us beyond the point at which chemists were left by Dobereiner, Pettenkofer, Dumas, and numerous other chemists who, for three-quarters of a century, have directed attention to such numerical relationships. In some respects—such, for example, as in the exactness with which the atomic weight of an element is the arithmetical mean of the elements above and below it in the same series—Mr Wilde's numbers express the relationship more closely than those of any other author, but this agreement is simply brought about by forcing the atomic weights into the requirements of the case. The increase in density as the odd and even series are ascended, is nothing more than an imperfect way of stating the well-known relationship between atomic weight and atomic volume, which is so much better shown by Lothar Meyer's curves. The table of elements presented by Mr Wilde ignores that fundamental principle of periodicity or recurrence of properties which is the keynote of Mendeléeff's system, and which has led to the general adoption of that system by chemists. We do not pretend that Mendeléeff's classification is faultless, the illustrious founder of the Periodic Law would be the first to admit that his system has certain imperfections. Mr Wilde has emphasized a few of these in his preface, and he somewhat summarily dismisses the whole scheme in the following words —

From the numerous discrepancies which present themselves in the classification of the elements when arranged in the regular order of their atomic weights, it will be obvious that the idea of recurring properties or periodic functions, in terms of the vertical series of Newlands or the horizontal series of Mendeléeff, has no more relation to chemical science than the law of the increase of population, or the laws of variation and inheritance in organic species.

This paragraph, penned in the present year, will, perhaps better than any other statement that could be reproduced from the paper, enable chemists to form a correct estimate of the value of the work and of the author's qualifications for dealing with the question of the origin of the chemical elements. R. MELDOLA.

<sup>1</sup> "Stannic and titanous oxides resemble silica both physically and chemically; they might be expected to form analogous compounds, and be isomorphous with silica, as Mariignac (1859) found actually to be the case." Mendeléeff's "Principles of Chemistry," vol. ii p. 95.

## NOTES

By the death of Lord Tennyson not only does England lose one of her noblest sons, but the world loses the Poet who, above all others who have ever lived, combined the love and knowledge of Nature with the unceasing study of the causes of things and of Nature's laws. When from this point of view we compare him with his forerunners, Dante is the only one it is needful to name; but although Dante's knowledge was well abreast of his time, he lacked the fulness of Tennyson, for the reason that in his day science was restricted within narrow limits. It is right and fitting that the highest poetry should be associated with the highest knowledge, and in the study of science, as Tennyson has shown us, we have one of the necessary bases of the fullest poetry—a poetry which appeals at the same time to the deepest emotions and the highest and broadest intellects of mankind. Tennyson, in short, has shown that science and poetry, so far from being antagonistic, must for ever advance side by side. We are glad to know that the Royal Society, of which Lord Tennyson has been for many years a Fellow, was fittingly represented at his funeral by its President and officers.

We regret to announce the sudden death of Mr. Robert Bullen, the curator of the Glasgow Botanic Gardens. He was well known as a horticulturist, being especially successful in the cultivation of orchids. The post vacated by his death is one of the best of the kind in the country, and we understand that the appointment will rest with the Corporation of Glasgow, who took over the management of the Botanic Gardens in 1891.

THE death of Dr. Léon Poincaré, professor in the Faculty of Medicine at Nancy, is announced. He died on September 15 at the age of sixty-four.

AT the meeting of the Linnæan Society of New South Wales on August 31, Mr. H. Deane, Vice-President, who occupied the chair, referred to the loss the Society had sustained by the death of Mr. R. D. Fitzgerald, well known for his knowledge, and for his artistic delineations, of Australian orchids.

RUSSIA, which already possesses some of the best equipped chemical laboratories in Europe, is to have another which is to eclipse all others. On September 13/25 the foundation stone of the new chemical laboratory of the University of St. Petersburg was laid with befitting ceremony. The new laboratory, which is designed by Prof. Mentschatkin in collaboration with the architect Krasowsky, is based upon the best existing models in Germany and Austria.

In the *Times* of the 10th inst. there is an announcement that Surgeon-Major Laurie has proved that the fall of blood-pressure in animals rendered insensible by chloroform is due to the action of the anæsthetic on the brain, and not on the heart. When blood containing chloroform is allowed to reach the brain only all the ordinary phenomena of anæsthesia are observed, but when such blood is conveyed to every other part of the body except the brain, which, by a peculiar arrangement of the experiment, is supplied with pure blood, the anæsthetic effects of chloroform and also its depressing effects on the circulation are not observed. We are glad to see that Dr. Laurie is still continuing his experiments on a subject of such vital interest, and we trust that his energy and the generosity of the Nizam, to which we owe the elaborate work of the Hyderabad Chloroform Commission, will meet an ample reward.

THE British Ornithologists' Union, founded in 1858, consists of upwards of 250 votaries of this branch of natural history, who maintain as their organ the well-known ornithological journal, *The Ibis*, now in its thirty-fourth volume. The more active members of the union have just formed themselves into a club, and will meet together once a month to read and discuss papers and to exhibit specimens. The first meeting of the "British

Ornithologists' Club" will be held on October 19. Mr. Howard Saunders, F.Z.S., is the treasurer and secretary.

THE university of Padua is about to hold a festival in honour of Galileo. The seventh of December, 1892, will be the tercentenary of the day upon which Galileo ascended the chair of mathematics at that university. In the words of the letter of invitation which the rector, Prof. Carolus Ferraris, has just issued to some of the learned societies of Europe, "Illo enim die Ann. mdcxii summus acerrimusque investigator legum, quibus caelestium terrestriumque rerum natura continetur, hic cathedram ascendit eamque voce sua immortalitati commendavit." It is to the honour of Padua that it welcomed Galileo to this high position the very next year after he had been publicly hissed and obliged to resign his professorship at Pisa. The festival will extend from the 6th to the 8th of next December.

THE Linnæan Society of New South Wales has just issued a second circular with respect to the Macleay Memorial Volume by which it appears that only £170 has been contributed out of £400 which is required for the publication of the Memorial Volume. The circular calls to mind Sir William Macleay's contributions to science, in purchasing and fitting out at his sole expense the ship *Chevert* and exploring the island of New Guinea, and in presenting to the University of Sydney his entire collection valued at £23,000, together with £6000 to provide salary for a curator. Sir William Macleay was also the founder of the Linnæan Society of New South Wales, for which he erected a suitable building, and which he endowed with the sum of £20,000. He further founded a chair of bacteriology and four scientific fellowships at the University of Sydney, at a cost altogether of £47,000. The sum of £170 seems hardly adequate as a recognition of these munificent gifts to science, to say nothing of the original researches which Macleay himself conducted.

MR. THOMAS HODGKINS, of Long Island, New York, has sent to the Royal Institution no less than £20,000 for the promotion of scientific research. Not very long ago, as we noted at the time, Mr. Hodgkins presented £40,000 to the Smithsonian Institution at Washington.

THE Severn Valley Field Club has completed the work of the current year. It has paid some attention to the glacial deposits at Gloppa, near Oswestry, which have recently yielded to Mr. A. C. Nicolson a large series of fossils. The members have also visited the Triassic rocks of the area round Warwick. Their work concluded with an investigation of the Uriconian and Longmyndian formations of Western Shropshire under the guidance of the President, Dr. C. Calloway.

DR. J. M. MACFARLANE has been appointed to the chair of Biology in the University of Pennsylvania, Philadelphia. He formerly held the post of senior assistant in the Botanical Department of the University of Edinburgh.

AN influential association has been formed for the promotion of the study of the Hausa language and people, in commemoration of the services of the Rev. J. A. Robinson, who died last year at his work as a missionary in the Niger Territories. Hausa is the *lingua franca* of the Central Sudan, extending from the Sahara to the tribes near the Gulf of Guinea, and from the Egyptian Sudan to the French colony of Senegal. Mr. Robinson convinced himself that no satisfactory work of any kind could be carried on among the races of the Central Sudan without a knowledge of Hausa. The Executive Committee of the new Association have decided to endeavour, with the least practicable delay, to appoint two "Robinson Students," conversant with Arabic or Hebrew, whose preliminary labours would be carried on in the comparatively temperate climate of Tripoli, with a view to their proceeding at a later date to the Central Sudan, where they would make the language and cus-

toms of the Hansas subjects of careful study. All scientific observations collected by these students during their residence in Africa will be sent to the Association for distribution to the appropriate societies.

THE Association of American Agricultural Colleges and Experiment Stations will hold its sixth annual convention at New Orleans on November 15. The different subjects assigned to station workers for the Columbian Exhibition will be discussed.

PROF. H. MARSHALL WARD, F.R.S., of the Royal Engineering College, Cooper's Hill, will give a course of ten lectures at University College, London, on "The Morphology and Physiology of Fungi and Schizomycetes." The course will begin on Thursday, October 13, at 3 p.m., and be continued at the same time each week till Christmas.

A LARGE plant of *Fourcroya* is now in flower in the conservatory of the Royal Botanic Society. The secretary of the Society referred to it at the meeting of the Council on Saturday last. The plant is sometimes called the century plant, the idea being that it flowers only once in a hundred years. In reality the flower is produced only once in the life of the plant, the duration or term of life varying considerably, according to the treatment the plants individually receive. Specimens of the *Agave Americana* have flowered in the Royal Botanic Society's garden, the ages of them being well authenticated as over 80 years; but the plant is known to flower in warmer climes before twenty years of age. The present specimen of *Fourcroya* is between twenty and thirty years old. It began on August 1 last to produce its flower spike, which, although the plant is slow growing generally, developed at a rapid pace, so that on September 15 the tip had reached the glass roof. A square of glass being removed, the flower spike continued its growth, and it is now some 3 feet or 4 feet above the ridge, a total of over 30 feet in height. The leaves vary from 6 feet to 7 feet in length.

In his treatise, "On the Propagation of Electric Force," Prof. Hertz mentions some experiments tending to prove that the production of resonance and the period of oscillation in resonators are not influenced by the specific resistance or the magnetic properties of the secondary conductor. But if the phenomena be observed electrometrically, the individual properties of the metals soon show themselves. This method was employed by Mr. V. Bjerknes, of the University of Christiania, who gives an account of his results in No. 9 of *Wiedemann's Annalen*. Experiments made with copper, brass, German silver, platinum, nickel, and iron show that metals have different powers of absorbing the energy of electric waves. The rate of absorption increases with the resistance and with magnetization of the metal. Iron and nickel were able to follow the oscillations to a certain extent, which means that their magnetization was actually reversed one hundred million times per second.

A method of exhibiting the Hertzian oscillations to a large audience is described in the same number by Mr. L. Zehnder, of the University of Freiburg. The two conducting rods placed in the focal line of the concave mirror are connected with a Geissler tube, within which the ends are placed very closely together, but so that a discharge produces not a spark but a general luminosity inside the tube. The secondary Hertz effects are too feeble to be visible except at a very short distance and in a darkened room. In this case they are augmented by a kind of relay. On either side of the terminals of the resonator are two other terminals from a circuit of 600 secondary cells, which can be regulated so that the current is just unable to traverse the distance between the terminals. As soon, however, as the resonator responds to electric oscillations, the relay is brought into action, and a brilliant discharge takes place. In

cases where such a large accumulator is not available, it is possible to work with another inductorium, or, still better, to obtain the oscillating current from the primary coil by bringing one end of a wire into its neighbourhood, the other being led to earth. By such means it is possible to exhibit the phenomena in question without even darkening the room.

THE weather during the first part of the past week was very boisterous and inclement over the whole of these islands. Between Thursday, the 6th inst., and Monday last, two deep depressions closely following each other passed over the country from off the Atlantic, and heavy gales were experienced in all parts of the United Kingdom, accompanied by much rainfall, while thunderstorms and hail occurred in many places. The sea also was exceptionally rough, especially on our north-west coasts, and caused much damage on shore. Temperature was somewhat low for the time of year, the daily maxima rarely reaching 60° in any part, while the nights were very cold. As the depressions passed to the eastward the weather cleared and the temperature decreased considerably, sharp frost occurring on the ground over the inland parts of England. Towards the close of the period the type of weather was becoming more settled in character than it had been for some time past, but on Tuesday a depression lay over the Bay of Biscay, which might disturb our conditions. The *Weekly Weather Report* of the 8th inst. showed that during that week the rainfall exceeded the mean in all districts except the south of Ireland, and that temperature was from 2° to 4° below the mean, the lowest of the minima ranging from 32° to 38°. The only district in which bright sunshine exceeded the mean was the Channel Islands, the percentage of the possible duration amounted there to 40, while it was only 8 in the north of Scotland.

THE Meteorological Council have published the hourly means obtained from their self-recording instruments at four observatories for the year 1889, for periods of five days, calendar months, and for the year, while means of pressure and temperature and totals of rainfall are also given for every day. This is the third year in which the observations have been published in this form, instead of the actual hourly values, as formerly, and an addition has been made by including the monthly and yearly mean values of the daily maximum and minimum temperatures for this and the two previous years in this volume. The work contains 112 quarto pages of very clearly drawn up tables.

MR. H. DEVAUX has been making interesting experiments on the sense of taste in ants. Among other results he has found that *Lasius flavus*, while fond of sugar, dislikes saccharine. The ants swarmed around sugar laid out for them, but turned away from saccharine as soon as they tasted it. Even sugar became unpleasant to them when it was mixed with saccharine. It seems, therefore, that sweetness is not the only quality which attracts them to sugar.

PROF. SCOTT has a note in the new volume of "the Transactions and Proceedings" of the New Zealand Institute, on the occurrence of cancer in fish. The fish afflicted with this disease were all specimens of the American brook-trout (*Salmo fontinalis*) kept in confinement in one of the ponds at Opoho belonging to the Dunedin Acclimatization Society. Males and females were alike affected, and the diseased fish never recovered. Prof. Scott has been able to examine several specimens showing the disease in various stages of advancement, and gives in his paper a short account of the naked-eye and microscopic appearances of the growth. The occurrence of cancer in the lower animals has been frequently observed of late years, and it is by no means so rare among them as it was at one time thought to be. Prof. Scott does not, however, know that it has ever before been noted in fish.

IN his report as surgeon-naturalist of the Marine Survey of India, to which we referred last week, Dr A. Alcock records some interesting observations on the little estuarine crab *Gelasimus*. The most obvious structural peculiarity of *Gelasimus* is the enormous development of one of the chelæ in the male only, the chelæ in the female being minute. The species observed by Dr Alcock was *Gelasimus annulipes*, Edw. This species lives in vast swarms in "warrens" on the muddy tidal swamps of the Godavari and Kistna, each individual having its own burrow, round which it ranges, and into which it retreats when alarmed. In the colder months, at any rate, the males far outnumber the females. In a fully adult male the length of the large chela is two-and-a-half times the greatest length, and one-and-a-half times the greatest breadth, of the whole body, and 40 per cent of the entire weight of the animal, and is coloured a beautiful cherry-red fading to a rose pink, the rest of the animal being of a dingy greenish-brown colour. Dr Alcock has been able to observe that, whatever other functions the great chela may serve, it also, in the species under consideration, is (1) a club used in the contests of rival males, and (2) a signal to charm and allure the females. This last function is particularly apparent. As one walks across the mud one first becomes aware of the presence of these crabs by noticing that the surface of the mud is everywhere alive with twinkling objects of a brilliant pearly-pink colour. Carefully watched, these prove to be the enormous chelæ of a crowd of males of *Gelasimus* waving in the air, each little crab standing at the mouth of its burrow and ceaselessly brandishing its big claw. On closer observation, among every ten or so males a small clawless female may be seen feeding in apparent unconcern. If the female should approach the burrow of a male, the latter displays the greatest excitement, raising itself on its hindmost legs, dancing and stamping, and frantically waving its beautifully coloured big claw. From prolonged watching, Dr Alcock feels convinced that the waving of the claw by the male is a signal of entreaty to the female, and he thinks that no one can doubt that the claw of the male has become conspicuous and beautiful in order to attract and charm the female. The second function, as a fighting weapon, becomes apparent when in the general tournament one of the rival males approaches too close to another. The great claw is then used as a club, the little creatures making savage back-handed sweeps at each other.

AN excellent paper on fungous diseases and their remedies was read lately by Prof J. E. Humphrey before the Massachusetts Horticultural Society, and has now been printed. One of the principles on which he insists is that the treatment of these diseases, to be efficient, must be preventive rather than remedial. He points out that it is not enough to take care that plants shall have abundant nourishment. No practice, he says, is more common among American fruit growers than to leave in the vinery and the orchard, lying on the ground or hanging from the branches, the dead fruits of the season, which have been rendered worthless by fungi. Nothing could produce more unhealthy conditions, for these dead fruits commonly furnish to the fungi which attack them precisely the most favourable soil for further and complete development. In the next spring the air is full of the spores of these fungi, which find lodgment on the new leaves and fruits of the very plants on which they grew last year, and so the story goes, year after year. "In a word," says Prof Humphrey, "keep your orchards and gardens and greenhouses clean. Allow no rubbish to be about on which fungi can breed. Remove and destroy all diseased fruits or plants as scrupulously as you preserve saleable ones, and you will have more saleable ones to preserve. It is surprising how far generous culture and clean culture will go toward preventing fungous diseases, without special treatment."

NO. 1198, VOL. 46]

THE Marquis de Nadaillay contributes to *Science* (Sept. 23) an interesting account of the various discoveries which have been made in the caves of Baoussé Roussé, between Mentone and Ventimiglia. The caves were found in 1872 by M. Rivière, who has since vigorously prosecuted his excavations. These have yielded many human skeletons, all belonging to the Cro-Magnon race. They are robust, and bespeak an athletic constitution and great muscular power. The men were remarkably tall, the crania are dolichocephalic, and the tibiae platycnemid. The bones of all the adults, after the total decomposition of the flesh, were painted red with the help of peroxide of manganese or other substances frequently met with in the caves—a custom which the Marquis de Nadaillay believes prevails, or till lately prevailed, among some Indian tribes. Much attention has been devoted to the latest discovery, made early in the present year, of three skeletons—a man, a woman, and a "young subject," whose wisdom teeth had not been developed. They were found eight metres below the ground, and had been buried on a bed of cinders, broken fragments of charcoal, and remains of all sorts, evidently the hearth on which the family cooked their victuals. The boy wore a necklace formed of two rows of the vertebrae of a fish and one row of small shells. At different points hung pendants cut out of the canine teeth of stags, decorated with parallel striæ. The man had also a necklace of fourteen canines of the stag, also striated. With the skeletons were found stone instruments, some of them finely worked, but none of them polished, and some bone implements of very rude fabrication. The man was very tall. If we judge by the length of his thigh bone, his height must have exceeded six feet six inches. The teeth even of the boy were very much worn, those of the man were worn to the roots. The bones of many mammals have been found, but none belonging to extinct species, or even to the reindeer. On the other hand, no polished stone implement has been discovered. The remains, therefore, must be ascribed to the end of the quaternary or the beginning of the neolithic times. One cave is still unexcavated. The Prince of Monaco, whose property it is, has given orders that the excavations are to begin next spring.

MR. C. HEDLEY read before the Linnæan Society of New South Wales, on August 31, a paper in which he presented an interesting study of ancient geography. The immediate subject was the range of *Placostylus*. He remarked on the essential unity of the *Placostylus* area as a zoological province, embracing the archipelagoes of Solomon, Fiji, Hebrides, Loyalty, New Caledonia, Norfolk Island (?), Lord Howe, and New Zealand—a unity explicable only on the theory that they form portions of a shattered continent, and are connected by shallow banks formerly dry land. Deep sea soundings, especially those of the *Challenger* in the Coral Sea, further demonstrate the existence of such a submarine plateau, for which the name of "The Melanesian Plateau" is proposed. Further, Mr. Hedley contended that the Melanesian Plateau was never connected with, nor was ever populated from, Australia, that its fauna and flora were originally derived from New Guinea.

In the *Proceedings* of the U. S. National Museum (vol. xv), Lieut. Dix Bolles calls attention to an interesting object included in a collection of ethnological specimens given by him to the museum in 1883-85. This is a wooden mask, which has for its eyes two large bronze Chinese coins. The grave from which the mask was taken is near the Chilcat village, at the mouth of the Chilcat River, Alaska, where stands a row of six grave-houses on a narrow strip of land close to the river, with a swamp behind them. From this particular grave very little was obtained by the explorers, its contents having nearly all rotted away. Lieut. Bolles was told by the natives that it

was the grave of a medicine man who had flourished more than 200 years before, six successors having filled his office, each one living to a good old age. Careful questioning failed to evoke any other answer. When the coins were shown to the Chilcats, they could not remember having ever seen such objects. Lieut. Holles concludes that the coins probably were derived from a junk driven on the coast about two centuries ago. "To those," he says, "who doubt the advent of junks on the west coast at this early date, these facts will probably not be satisfactory, but it will be necessary for them to break down by direct evidence such a strong plea."

MESSRS H. ATABASTER, GATEHOUSE & CO have now in the press, shortly to be issued, a new work, entitled, "Domestic Electric Lighting, treated from the Consumer's Standpoint." The author is Mr. Ed. C. de Segundo.

"THE ELECTRICIAN" Printing and Publishing Co., Limited, have in preparation for their "Electrician" Series the following volumes:—"Electromagnetic Theory," by Oliver Heaviside, "Electrical Engineering Formulæ, &c.," by W. Geipel and H. Kilgour, "Submarine Cable Laying and Repairing," by H. D. Wilkinson, "Drum Armature Winding and Commutators in Theory and Practice," by F. M. Weymouth, and "Electricity as a Motive Power," by Albion T. Snell, M.I.C.E., M.E.

THE first series of lectures given by the Sunday Lecture Society begins on Sunday afternoon, October 23, in St. George's Hall, Langham Place, at 4 p.m., when Dr. Andrew Wilson will lecture on "The Distribution of Animals and what it teaches." Lectures will subsequently be given by Mr. Willmott Dixon, Prince Kropotkin, Mr. R. Brudenell Carter, Mr. Arthur W. Claydon, Prof. H. Marshall Ward, F.R.S., and Dr. E. E. Klein, F.R.S.

ANOTHER memoir upon persulphuric acid and the persulphates is contributed by M. Berthelot to the *Annales de Chimie et de Physique*. As described in our note of vol. xiv, p. 577, the potassium, ammonium, and barium salts of this interesting acid were obtained last year by Dr. Marshall, of Edinburgh, in tolerably large quantity and in well developed crystals. M. Berthelot, to whom the honour of the first preparation of persulphuric acid and its anhydride is due, now publishes his further work upon the subject, fully confirming Dr. Marshall's results, and adding a few more facts to our knowledge of the acid and its salts. The form of electrolysis apparatus which has been found by M. Berthelot to yield the best results consists of a double cell, the inner vessel of which is constructed of porous porcelain. The liquid contents of both the interior and exterior vessels are cooled by means of glass worms through which a constant current of cold water is maintained. The inner cell of 150 c.c. capacity contains a concentrated solution of potassium or ammonium sulphate, according as potassium or ammonium persulphate is required, in sulphuric acid diluted with six or seven times its volume of water. The nearer the composition of this liquid approaches to that of a solution of bisulphate of potassium or ammonium, the greater is the yield of persulphate. The exterior cell is simply filled with dilute sulphuric acid. The positive pole in the interior cell is most advantageously formed by a stout platinum wire, about one millimetre in diameter, as persulphuric acid is found by M. Berthelot to be rapidly decomposed in contact with a large surface of platinum. Platinum sponge, indeed, instantly decomposes the acid or solutions of its salts. The negative pole in the outer cell may conveniently take the form of a large plate of platinum. The current employed was one of three amperes derived from accumulators. At the expiration of fifteen to twenty hours the internal cell is found to contain large quantities of beautiful crystals of the persulphate. The usual yield of the potassium salt was 20.25 grams, and of

the more soluble ammonium salt as much as 40-45 grams, in one operation. M. Berthelot has also obtained potassium persulphate by the direct electrolysis of sulphuric acid and subsequent addition to the product of a concentrated solution of potassium bisulphate, crystals of potassium persulphate,  $\text{K}_2\text{S}_2\text{O}_8$ , being at once deposited. This mode of preparation is not so advantageous as the method of production by the electrolysis of potassium sulphate as above, but affords interesting proof of the formation of free persulphuric acid by the electrolysis of oil of vitriol. M. Berthelot has further succeeded in preparing persulphuric acid by the gradual addition of anhydrous barium peroxide to concentrated sulphuric acid in a small flask surrounded by ice. So rapid is the action that if the addition of the peroxide is continued until the sulphuric acid is almost exhausted, even although the vessel is maintained in pounded ice, dense vapours are evolved which possess the remarkable odour and other properties of persulphuric anhydride. Another interesting fact observed by M. Berthelot is that a solution of potassium persulphate attacks mercury, even at the ordinary temperature, with production of a yellow basic sulphate which appears to be identical with the salt known since the times of the alchemists as *turpith mineral*.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Miss F. A. Hill, two Racoons (*Procyon lotor*) from North America, presented by Captain Sharp, a grey Ichneumon (*Herpestes gresseri*) from India, presented by Mrs. Wyndham Hewes, a Stanleyan Chevrotain (*Tragulus stanleyanus*) from Java, presented by Mr. Chas. J. Noble, a Vulpine Phalanger (*Phalangista vulpina*, ♂) from Australia, presented by Master H. H. Barret, a White Stork (*Ciconia alba*), European, presented by Sir H. Rae-Reid, Bart., F.Z.S., an Ostrich (*Struthio camelus*, ♂) from Africa, presented by H. M. the Queen, a Common Chameleon (*Chamaeleon vulgaris*) from North Africa, presented by Mrs. Davidson, three Negro Gamrins (*Nidas ursulus*) from Guiana, a Canarian Laurel Pigeon (*Columba laurivora*, ♂) from the island of Gomera, Canary Islands, two Nicobar Pigeons (*Columba nicobarica*) from the Indian Archipelago, deposited, an Indian Muntjac (*Cervulus muntjac*, ♀) from India, four Ringed Plovers (*Ægialitis hiaticula*) and two Dunlins (*Tringa alpina*), British, purchased

#### OUR ASTRONOMICAL COLUMN

LUMINOUS NIGHT CLOUDS.—In an article communicated to *Astronomische Nachrichten*, No. 3120, Herren W. Foerster and O. Jesse invite astronomers and geophysicists both here and abroad to make observations of the very interesting phenomena of luminous night clouds, the appearance of which has, up till now, been observed more or less only at Berlin. Since the year 1885, the authors tell us, these appearances have been most noticeable, and it is because they are now becoming less so that they wish to have as many observations made as possible. The phenomenon appears in the form of cirrus clouds, which stand out bright against the twilight sky. The colour generally noticed is that of a bluish white, and when the horizon is approached, gold and red tints are added. The best time for observation is said to be just before and after sunrise and sunset. From photographs taken at Berlin it has been computed that these clouds are at a height of 82 kilometres. Long after the sun has set they are seen to reflect the sunlight, but as soon as they fall within the reach of the earth's shadow they immediately become invisible. The observations show, so far as may be judged from those already at hand, that the movements of this phenomenon after midnight are directed from the north east  $\pm 40^\circ$ , and the authors think it highly probable that the resistance of the medium surrounding the earth accounts for these movements. This is to a certain extent affirmed by observations made at Punta Arenas and other places, the phenomena occurring six months after the conclusion of the Berlin observations. The authors suggest that eye observations

(taken every few minutes) should be made in different latitudes, to ascertain the apparent height to which these clouds attain. The determinations of azimuth and altitude should also be current to three or four minutes of arc, and the time to two or four minutes. Notice should also be taken of the general state of the atmosphere at the time of observation, while photography should be employed to record their place and motion. The paper contains one or two more suggestions, among which is the employment of the spectroscope, and concludes with the hope that the importance of this phenomenon in relation to cosmical problems will arouse much interest and enlist many observers, for, in such a case as this, the observations of one institution will not help to solve such a general question as this.

**NOVA AURIGÆ**—From the communications, in *Astronomische Nachrichten*, No. 3120, we make the following notes with reference to the magnitude and spectroscopic appearance of the Nova Aurigæ.

Dr J. Holetschek, of the Vienna Observatory, has examined the star with regard to the former, and finds that, if any, an increase in brightness has taken place since August 24. The following are his figures, N standing for the Nova, and  $\alpha$  a neighbouring star, the magnitude of which is taken as 9.7. The hours refer to Vienna mean time.—

1892	h	N	m
August 24	13½	0.5 $\alpha$	9.65
" 26	14	2 $\alpha$	9.5
" 27	14	1.5 $\alpha$	9.55
" 28	12½	2.5 $\alpha$	9.45
" 30	12½	2 $\alpha$	9.5
Sept 2	14	3 $\alpha$	9.4

Observations made on Sept. 15 12h, Sept. 16 11½h, and Sept. 17 12½h showed that N was at least four degrees brighter than  $\alpha$ , and two degrees brighter than the star, 9.5m B.D. + 30° 924.

Using the 30 inch of the Pulkova Observatory, Mr. A. Bilopolsky has made some measurements of the brightest line visible in the spectrum. His measures are—

1892	W. L.	Mean
September 10	501.2 $\mu$	
" 12	501.1	
" 14	(499.5)	501.0
" 15	500.9	
" 16	500.7	

Of the other lines there were seen D or D<sub>3</sub>, F, and a dark line about wave length 465 $\mu$ .

**MINOR PLANETS**—The application of photography to the search of minor planets seems to be rewarded with remarkable success, for no less than four new ones, 1892, E, F, G, and H, have, since September 25, been discovered. The first two are due to M. Perrotin, while the last two were photographed by M. Wolf. A fact worth recording is that the plate, on which the latter planets were found, contained also two other images, those of the planets (34) Circe, and (184) Dejopeja, thus the positions of four planets were obtained with one exposure.

**REPORT OF MR. TEBBUTT'S OBSERVATORY**—In this small pamphlet we have a condensed account of the present state of the observatory buildings, instrumental equipment, &c., together with the work done during the year 1891. Although the staff is not very great, yet the work carried out shows that all the available time has been made the most of. The observations include forty-six occultations of stars by the moon, phenomena of Jupiter's satellites, transit of Mercury, conjunction of Venus and Jupiter, and filar micrometer comparisons of the minor planet Ceres, comprising 106 comparisons and four comparison stars. Several comets were observed with the square bar-micrometer, while some interesting double stars and the two variables of Argus and R. Carinae have also been worked at. The 9h. a.m. meteorological observations have been continued with the usual regularity.

**PHOTOGRAPHIC CHART OF THE HEAVENS**—In a paper read on July 1, 1891, before the Royal Society of New South Wales, Mr. H. C. Russell relates many of his experiences, together with some of the results obtained during the preparation of the Sydney Observatory for the photographic chart of the heavens. The first difficulty that turned up had reference to the photographing of the stars of the fourteenth magnitude. The two

minutes' exposure was found quite long enough for ninth magnitude stars, but the thirty minutes was not sufficient to record those of the fourteenth. A question also arose as to coloured stars, for in many cases stars visible telescopically were not photographed at all. Of the many objects photographed with the portrait camera, Mr. Russell describes very fully the beautiful nebula 30 Doradus. This nebula, as he says, is a great spiral structure, of which we see the greatest diameter, its thickness measured through in the line of sight being comparatively small. He has been able also to obtain a very fine photograph of N. Argus, a nebula, which, as may be concluded from the negative, "covers a much larger area than that of Orion." The same photograph also confirms the observations made by Mr. Russell in 1872 that a conspicuous part of the nebula which Herschel drew and described in 1838 has wholly disappeared, and that its place is now occupied by a dark round spot. What this may be is a doubtful question, but as Mr. Russell says "It cannot be a solid body, because the stars are there, but a slight misty body would hide the nebula and not affect the stars very much." The pamphlet concludes with an excellent picture of the  $\kappa$  Crucis cluster.

### GEOGRAPHICAL NOTES

COLONEL BAILEY, R. E., lecturer on Forestry in the University of Edinburgh, has been appointed secretary to the Royal Scottish Geographical Society, in room of Mr. A. Silva White, whose resignation on account of ill-health we noticed some months ago.

PROF. CHERSKI, whose projected journey in Eastern Siberia was mentioned in Geographical Notes for June 30 (p. 212) is reported to have died near Sredne Kolymsk, on his way down the Kolyma river towards Nizhne Kolymsk, where he intended to have passed the winter. Cherski has travelled frequently and far in Siberia, and has done much to elucidate the geographical conditions, and in particular the geology of many parts of Northern Asia. His great geological map of the Lake Baikal district is the work by which he will be best remembered.

The current number of the *Scottish Geographical Magazine* contains Mrs. Bishop's account of her travels in Ladak and the adjacent territories, often called Lesser Tibet. As a record of personal adventure and observation of native character the paper ranks worthily with the published records of this traveller's earlier and later journeys.

THE *Proceedings* of the Royal Geographical Society for October publishes a short statement of the progress of Indian surveys during the last field season. In Bengal the Behar detachment completed the traverse survey of 1610 square miles in districts Muzaffarpur and Champaran. In Bombay 2536 square miles of detailed survey were completed on the scale of two inches to one mile, and 2100 square miles were triangulated in the Gujarat and Mahratta country. Two parties were at work in Burma. In district Sagaing 1842 square miles of cadastral survey and 1142 of traverse survey were completed, while 700 square miles of traverse survey were made in district Shwebo, and a topographical survey, on the scale of one mile to an inch, of 106 square miles of the Chindwin coalfields. There were also carried out in districts Amherst, Tavoy, and Mergin 881 square miles of cadastral survey, besides a traverse survey of 510 square miles.

### THE MICRO-ORGANISMS OF THE SOIL<sup>1</sup>

THE high office with which you have honoured me entails the delivery of an address, which I keenly feel I cannot give in keeping with the standard set by my distinguished predecessors.

Fermentation, though observed since pre-historic times, is perhaps less understood than any chemistry has to deal with. The excitors of fermentation are rendered exceedingly difficult of investigation, because they, like all living things, are subject to physiological—or more specially pathological—functions of life, they are so sensitive that any abnormal influence either changes their whole mode of existence or destroys it altogether; a medium suitable to the life of one special kind is changed by

<sup>1</sup> Address delivered by Prof. Alfred Springer as Vice-President of Section C, at the meeting of the American Association for the Advancement of Science.

it into a product which ceases to sustain it, but can nourish a lower class of organisms whereby concomitant fermentations arise, whose united effects are frequently such as to completely modify those produced by each separately, and for this reason have the specific actions of some ferments either totally escaped observation or have been misconstrued. Every succeeding year brings additional proof of the important role played by these minute organisms, and to such an extent, especially, has this been the case in connection with the rendition of available nitrogen, that there are good reasons to believe that a clearer comprehension of the action of soil ferments will dissipate all the anxiety chemists now entertain as to a gradual diminution of this so essential nutrient.

To Hellriegel, Willfarth, Wollny, Engelmann, Winogradski, Warrington, and Heraus can be attributed the most noteworthy experiments in this special line. In order to appreciate the importance of their discoveries, I will, with your kind indulgence, first give a brief historical résumé of the study of fermentation. Owing to the extreme age of the use of alcoholic beverages, ferments entering into their production are best known, and this, added to the fact of their being larger and thus permitting of better examination, has been the determining cause of basing investigations and deductions upon their behaviour.

The very fact that the art of cultivating the vine and making wine is attributed by the Egyptians to Osiris, the Greeks to Bacchus, the Israelites to Noah—the brewing of beer to Gambrinus—shows how old these discoveries must have been. The effects of fermentation are sufficiently striking to have called the attention of primitive man to them. The ancient tribes of Asia and Africa understood how to ferment not only grape juice, but also to obtain alcoholic beverages from substances like starch, not directly fermentable. They used soured dough or beer-yeast as leaven for their bread, and knew how to prepare vinegar. The alchemists were wont to clothe their thoughts in such words as to make it difficult for us to decide what precise ideas they attached to the expressions of "Fermentation and Ferments" which are so frequently found in their writings of the thirteenth to the fifteenth century. They even speak of the philosopher's stone as fermenting unlimited quantities of lead and mercury into gold.

In the fifteenth century Basil Valentine in his "Triumphal Car of Antimony" claims that yeast employed in the preparation of beer communicates to the liquor an internal inflammation, thereby causing a purification and separation of the clear parts from those which are troubled, but considers alcohol as already existing in the decoction of germinated barley. In 1648 Van Helmont declared fermentation the cause of all chemical action and spontaneous generation, going so far as to give directions for the production of mice, frogs, eels, &c. He clearly observed the production of a special gas (gas vinorum) during alcoholic fermentation, and stated that something from the ferment passes into the fermentable substance, developing therein like a seed in the soil, thereby producing fermentation.

Willu, an English physician, in 1659 claimed that all functions of life depended upon fermentation, and that diseases were but abnormal fermentations. Both he and Stahl regarded a ferment as a body endowed with a motion peculiar to itself, which it imparts to the fermentable matter. Stahl in 1697 advanced the following theory: "Under the influence of the internal motion excited by the ferment, the heterogeneous particles are separated from each other, recombining so as to form more stable compounds, including the same principles but in different proportions." Putrefaction is but a particular case of fermentation. This theory remained unchallenged eighty years.

Lavoisier, by applying the new methods of organic analysis he had invented, quantitatively ascertained the relations between the fermented matter and the products.

Guy Lussac considered oxygen the sole cause of fermentation, putrefaction, and decay, by transmitting its motion to the ferment and this imparted its motion to the loosely combined fermentable mass.

The present theories of fermentation originated with Schwann and Pasteur. It took a century and a half before the experiments which led up to Schwann's theory found a scientific explanation by the work of this chemist. Leuwenhoeck had in 1680 already noticed that beer yeast was composed of small spheroid globules. Cagniard de Latour declared yeast a plant and the exciter of fermentation.

Schwann's experiments were made to determine the possibility of spontaneous generation. He found that fermentable

fluids, when first heated in closed vessels in the presence of oxygen, to the temperature of boiling water would not ferment. This disproved Guy Lussac's theory that oxygen caused fermentation. He next showed that purified air or oxygen passed into a sterilized fermentable fluid did not induce fermentation, but that this set in with the introduction of ordinary air. He concluded from these experiments that the air was not the exciter, but simply the medium containing it, and that in the floating particles of the atmosphere were organisms capable of developing in the fluid, should these be killed by heat, fermentation would not take place. In his examination of these organisms, although his methods were not absolute, his conclusions that alcoholic ferments are of a vegetable nature were correct.

Instead of general acceptance, Schwann's theory received but little recognition.

Schultze's method of first passing the air entering a sterilized fermentable fluid through oil of vitriol, and that of Schroeder and Dusch of filtering it through cotton can be regarded as modifications of Schwann's experiments. All these experiments conclusively show that the particles in the atmosphere are the exciters of fermentation but do not render them viable.

Pasteur, spurred on by the same motive as Schwann—namely, to determine the question of spontaneous generation—made a simple modification of Schroeder and Dusch's experiment, by substituting gun cotton, and achieved most remarkable results. The gun cotton, containing the particles filtered from the air, was dissolved in ether under the microscope, and now for the first time the organisms could be thoroughly examined.

Tyndall's well-known experiments, with the air tight box coated with glycerine, demonstrated that gravity alone can purify the atmosphere so as to debar fermentation from setting in.

Pasteur's theory is that "The chemical act of fermentation is essentially a correlative phenomenon of a vital act beginning and ending with it, there is never an alcoholic fermentation without there being at the same time organization, development, multiplication of globules, or the continued consecutive life of globules already formed."

The following few examples will serve to show that the slightest changes in nutrients may render them worthless as such to certain ferments and available to others. Organic substances showing optical rotation chiefly exist already formed in the animal or vegetable organisms, or they can be easily obtained from such substances formed during vital processes.

When these substances are made synthetically, they are chemically and physically similar to the natural isomers, but usually do not rotate the plane of polarized light. This leads to the belief that these synthetical products consist of active and inactive molecules in such proportions as to neutralize each other.

Pasteur<sup>1</sup> verified his hypothesis by splitting inactive racemic acid into dextro-tartaric acid. Neutral ammonium racemate in a solution to which the proper inorganic salts had been added was fermented by means of *Penicillium glaucum* and beer yeast. The dextro-tartaric acid was consumed and the lævo left.

Lewkowitch<sup>2</sup> took inactive mandelate of ammonia, employing either *Penicillium glaucum* or *Bacterium termo*, in each case at the end of several weeks all the fluids showed more or less dextro rotation. Natural mandelic acid from amygdalin is lævo rotary, therefore here, as in Pasteur's experiment, with racemic acid it showed that the organisms consumed the naturally produced isomer.

*Sac. ellipsoideus* and split fungi consume the dextro and leave the lævo. The dextro has the same positive as the lævo negative rotation. The melting points and solubility of the right and left are the same, yet we see that these substances, chemically and physically the same, save in their opposite rotatory powers, can serve in one case as nutrients to certain organisms, and the other are worthless as such.

#### *The Micro-Organisms of the Soil (Sacchse<sup>3</sup>).*

These organisms, according to their actions, can be divided into three groups. Those oxidizing constituents of the soil those reducing or destroying the same; and lastly those by whose activity the soil is enriched. As regards the first group the oxidation can take place in two ways—they can either oxidize by assimilating the organic substances of the soil and re-

<sup>1</sup> Cr. xlii 615, 16, 198.

<sup>2</sup> Chem. Cent. Bl., 1889, vol. li. 169, 225.

<sup>3</sup> B. xvi 1505, 1569.

ducing them to carbonic acid and water, in order to obtain the necessary heat and energy, or they can oxidize by giving off oxygen. The first may be termed intra cellular, and the second extra cellular acting organisms. Amongst the intra cellular we have primarily, the usual ferments of decay, which assimilate and respire at the expense of the carbon compounds. In some cases the organisms have accommodated themselves to seemingly most remarkable materials for respiration, the combustion of which affords the necessary heat. Thus the Iron Bacteria of Winogradski<sup>1</sup> require ferrous carbonate for their life and development, oxidizing the same to oxide. This can be physiologically interpreted as a respiration process, the protoxide of the respiration material becoming the oxide of respiration product.

The Sulphur Bacteria are equally remarkable. Their cells are distinguishable by containing from time to time granules of amorphous sulphur. These organisms were formerly regarded as causing the formation of sulphuretted hydrogen in sulphur springs.

Winogradski<sup>1</sup> claims the reverse to be the case. They do not produce sulphuretted hydrogen but consume it, burning it partially first to sulphur, which deposits in the cell water, then completely to sulphuric acid, which passes out and forms sulphates from the carbonates of the surrounding water. When no more carbonates are present, the combustion of sulphur to sulphuric acid ceases. Physiologically this is also a process of respiration directed towards generating heat and energy, sulphuretted hydrogen is the respiration material and sulphuric acid the respiration product.

(Olivier<sup>3</sup> does not agree with Winogradski and De Rey Pailhade<sup>4</sup> claims the existence of a substance, philothion, in many plants and animal tissues capable of converting sulphur in the cold to sulphuretted hydrogen.)

Certain nitrification ferments can be regarded as intra-cellular. They may take up ammonia and give it off as nitrates, this process ceasing as in the case of the Sulphur Bacteria, when no more carbonates are present.

We now come to the discussion of two ferments, the concomitant actions of which have heretofore caused much confusion. Schloesing and Muntz were the first to observe nitrifying ferments, but to Warrington and Winogradski belongs the credit of isolating the nitrous from the nitric ferment, furthermore, the striking discovery of a colourless organism, capable of existing and performing its functions, in a medium totally devoid of organic material, and synthetically producing organic bodies independent of sunlight. The importance of this discovery cannot be over-estimated.

Warrington<sup>5</sup> succeeded in obtaining organisms from meadow soil, cultivated in a solution of ammonium chloride and calcium carbonate, which oxidized ammonia to nitrous acid, but had no effect on nitrates. Assimilating the carbon of the carbon dioxide, they require no organic substance for sustenance. They obtain from the oxidation heat of ammonia the necessary energy to dissociate the carbon-dioxide.

Winogradski<sup>6</sup> obtained the same ferment employing 1 gr. ammonium sulphate, 1 grm. potassium phosphate dissolved in 1 litre Zurich water, to which he added basic magnesium carbonate. After inoculating the sterilized fluid with the nitrifying agent every trace of ammonia disappeared the fifteenth day. He describes this ferment as being an elongated ellipsoid, the smaller diameter 0.9-1 Mkr, the larger 1.1-1.8 Mkr. The organisms congregate about a piece of carbonate, cover it with their gelatinous mass, and as the carbonate disappears the cells take the shape thereof.

(Although the two investigators do not quite agree as to the morphological attributes of the ferment, Warrington arrived at the same conclusions as Winogradski.)

Winogradski<sup>7</sup> has at last succeeded in isolating the ferment which converts the nitrites into nitrates. He employed gelatinous hydrate of silica, impregnated it with a fluid containing the cultivated nitrous ferment. This medium was next inoculated with strongly nitrifying soil from Quito, shortly afterwards two different organisms formed respective colonies, one of these was the one sought for. It was composed of irregularly shaped rods, dissimilar to the nitrous ferment of the same soil. He has since found this ferment in many other soils; it is capable of converting solutions of nitrites into nitrates.

Strange to say the isolated ferment from Quito does not oxidize ammonia, it produced neither nitrites nor nitrates when sowed in ammoniacal fluids, easily nitrified by the nitrous ferment.

In normal soils the nitrate ferment only produces nitrates even in the presence of a large quantity of ammonia, which does not retard the oxidation of the nitrites immediately after their formation.

Muniz<sup>1</sup> claims the existence of an ammoniacal ferment in the soil which converts organic nitrogen into ammonia, preparatory to nitrification.

#### Extra-Cellular Oxidation

In order to oxidize outside of the organisms, oxygen must be evolved by an assimilation process. Assimilation as an oxidizing cause, for conditions prevailing in the soil, has heretofore received no significance, since the evolution of oxygen, according to the generally accepted theories, depended upon light and chlorophyll, consequently the produced oxidation could only occur on the extreme outer surface. An exception to this heretofore unrestricted rule has been found by Engelmann<sup>2</sup> as well as one by Heraus. According to Engelmann,<sup>2</sup> *Bacterium photometricum* sharply discriminates between lights of different intensity and wave lengths. The influence of light upon the bacteria is directly proportionate to the intensity. When the intensity is suddenly decreased, the bacteria shoot backwards with opposite rotation (the author calling this a terror motion), consequently a well defined illuminated spot in an otherwise dark drop serves as a trap for these bacteria. They cannot leave, since the terror motion causes them to move back into the illuminated field as soon as they come to the dark outline.

The mobile forms principally congregate in the ultra red rays, i.e. physiologically in darkness, and in them as in the visible parts of the spectrum in places closely corresponding to the absorption bands of bacteriopurpurin. This constant ratio between absorption and photokinetic action clearly indicates that the prime effect of light is equivalent to the carbon dioxide dissociating processes of plants containing chlorophyll.

The bacteriopurpurin is a true chromophyll, inasmuch as it converts the actually absorbed energy of light into potential chemical energy. When lights of different colour were employed, the evolution of oxygen increased with the absorption of light by the Purple bacteria. This shows that the power of developing oxygen is not the specific property of a certain colouring matter, as these organisms contain no chlorophyll.

It is not surprising, therefore, that other organisms, either coloured or uncoloured, be found to possess the property of assimilating carbon in the absence of light and evolving oxygen. Such a discovery has now been made—Hueppe<sup>3</sup> substantiating a communication from Heraus that certain colourless bacteria produce from humus and carbonates, in the absence of light, a body closely resembling cellulose. Oxygen is liberated, but remains unobserved, as it is immediately used to oxidize the ammonia to nitric acid.

The next question is To which extent do the oxidizing organisms partake in the oxidation phenomena actually taking place in the soil? According to E. Wollny<sup>4</sup> the oxidation of carbon-dioxide is almost completely to be attributed to the activity of small organisms, of which Adameiz<sup>5</sup> estimated that there are about 500,000 to 1 gr soil. As in all such experiments, this conclusion is based upon the fact that no evolution of carbon-dioxide takes place, or is forced to a minimum, in a sterilized soil under otherwise favourable conditions.

#### Liberation of Combined Nitrogen

This may take place during putrefaction under the greatest possible exclusion of oxygen, or during decay in the presence of oxygen. It does not necessarily occur in all cases, or may not be observed owing to a reverse concomitant process, i.e., the fixation of nitrogen. Nitrogen losses can be expected during decay, on account of the action of the produced nitrous acid upon the amidlike dissociation of humous bodies, as well as in the formation of easily dissociable ammonium nitrites. A peculiar case of the disappearance of available nitrogen exists in the reduction of nitrates, as noticed by Springer,<sup>6</sup> Gayon and Dupetit,<sup>7</sup> and Deherain and Marquenne.<sup>8</sup>

*Organisms by whose Activity the Soil is Enriched in Nitrogen*

A distinction must be drawn between the higher and lower plants. It is a well-known fact that most plants cannot assimilate free nitrogen, whereas there are sound reasons for the belief that the legumes are exceptions to this rule. The explanation has been sought in the tubercles. These tubercles contain a tissue, consisting of thin walled cells filled with an albuminous substance, consequently they are richer in nitrogen than the roots; they have been regarded by some as pathogenic growths, by others as reserve reservoirs for albumin. We may now conscientiously assume that these tubercles arise through exterior infection, and that they are not normal growths.

Hellriegel and Wilfarth,<sup>1</sup> in their great work, state—"The legumes deport themselves quite differently from the non leguminous plants respecting the assimilation of nitrogen, whereas the latter are totally dependent for their nitrogen needs upon the nitrogen compounds present in the soil, and their development proportional to such disposable supply. The legumes have, besides, the soil nitrogen, a second source, from which they can abundantly cover any deficiency existing in the first. This second source is free atmospheric nitrogen. The legumes attain this power by the co-operation of active living micro-organisms. The mere presence of low organisms in the soil does not suffice to make the free nitrogen serviceable, but it is necessary that certain kinds of organisms enter into a symbiotic relationship with the legumes.

Lupines acquire nitrogen like the other legumes. They starve in a soil free from nitrogen when the presence of low organisms is excluded, but when this is not the case their growth is normal. The experiments were carried on in sand containing a suitable nutritive solution. Some of the pots were sterilized, to some infusions from soil were added. In all and in only those, to which fresh infusions of lupine soil had been added the lupines developed normally bearing the well-known tubercles on their roots, and contained, when harvested, conspicuously larger amounts of nitrogen than the soil and infusion could have given them. Wherever the infusion had not been added, or where it had been sterilized at 100 or even 70, the development remained abnormal, the production scant, tubercles remained absent and the harvested plants contained less nitrogen than had been offered them.

According to Ward,<sup>2</sup> Breal,<sup>3</sup> and Pradmowski,<sup>4</sup> tubercles will grow on plants free from them when infected with an infusion from tubercles of other plants.

Beyrenick<sup>5</sup> has named the infecting organisms, of which there may be many varieties, *Bacterium Radicola*. With the growth of the tubercles the behaviour of the plant towards nitrogen is changed, and the just mentioned independence begins, this has been proved by an almost superabundance of experiments. Still the explanation of the manner in which the nitrogen is acquired is not definitely settled. The first inference would be that the root-inhabiting bacteria possess the power of assimilating atmospheric nitrogen, and the higher plants as hosts harbouring these bacteria in their roots, use the nitrogen compounds so produced. Thus there would exist a case of symbiosis between Split Fungi and the higher plants. We cannot be too slow in accepting this seemingly simple explanation—still the difficulty of a correct interpretation does not alter the fact that the legumes acquire free nitrogen from the atmosphere, and that the refuse of their roots thus enrich the soil. They may be called nitrogen collectors in contradistinction to the graminaceous nitrogen consumers.

Berthelot<sup>6</sup> has long contended that the free soil can fixate nitrogen, he considers a sandy and clayey nature of the soil essential, it must admit of free access of air, must not be too moist, be rich in potash and poor in nitrogen. Gautier and Drouin<sup>7</sup> claim that the presence of humous substances causes increase of nitrogen.

Soils free from organic substances do not fixate nitrogen, or the gain is slight. The presence of ferric oxide so long considered capable of fixing nitrogen, has no effect. Berthelot, as well as most investigators in this line, attribute the fixation to the activity of nitrogen fixing chlorophyll free bacteria. In most cases the amount is much less than that obtained in soils with legumes. No inorganic soil constituents are known to

possess the power of fixing nitrogen, and it is questionable whether humous substances can directly do this.

In 1881 Atwater claimed that peas during their growth obtained large quantities of nitrogen from the air. Atwater<sup>1</sup> and Woods made another series of eighty-nine experiments, the result will be found in their admirable paper in the American journal. I will quote the following: "There was in no case any large gain without root tubercles, but with them there was uniformly more or less gain of nitrogen from the air. As a rule, the greater the abundance of root tubercles, the larger and more vigorous were the plants, and the greater was the amount of atmospheric nitrogen acquired. The connection between the root tubercles and the acquisition of nitrogen, which was first pointed out by Hellriegel, is abundantly confirmed. In a number of these experiments, there was a loss of nitrogen instead of a gain. The loss occurred where there were no root tubercles, it was especially large with oat and corn plants, and largest where they had the most nitrogen at their disposal in the form of nitrate. This loss may probably be due to the decomposition of the seeds and nitrates through the agency of micro-organisms. In brief, the acquisition of large quantities of atmospheric nitrogen by leguminous plants, which was first demonstrated by experiments here, and has been since confirmed by others is still further confirmed by the experiments herewith reported. These experiments in like manner confirm the observation of the connection between root tubercles and the acquisition of nitrogen. There is scarcely room for doubt that the free nitrogen of the air is thus acquired by plants."

Chemists, as a rule, hesitate to accept isolated cell life as modifying and conditioning the action of those more differentiated, yet it seems that all circumstances point to the fact that most reactions taking place between nitrogen and plants are influenced by micro organisms.

Let us hope that chemistry will, in the near future, score its greatest agricultural triumph, by unveiling the mysteries which still shroud the specific actions of these organisms, thus making it possible to supply the demands of a constantly increasing population.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—A course of instruction (Lectures and Laboratory work) in sciences bearing upon Agriculture will be commenced in Cambridge this term, it will extend over two years and will include the following subjects—Agriculture, Chemistry, elementary and agricultural, Botany, elementary and agricultural, some departments of Physiology and Geology, Agricultural Engineering, Surveying, and Mensuration. Arrangements will also be made for instruction in Book-keeping, and in Agricultural Law for those who desire it. The subjects taken this term will be Elementary Chemistry, by Prof. Liveing, and Elementary Botany, by Mr. Seward, of St. John's College. It is hoped that this course will prove useful to gentlemen intending to farm, or to manage their own land, and to those who are likely to become estate agents. Further information may be obtained from Mr. H. Robinson, at the University Chemical Laboratory, Cambridge. Prof. Foster announces a new intermediate course in Physiology, with laboratory work, especially for medical students, to be given by Dr. L. E. Shore, on Wednesdays and Fridays at ten, during the Michaelmas and Lent terms.

Dr. Donald Macalister, St. John's, has been appointed Assessor to the Regius Professor of Physics.

Mr. S. F. Dufton has been elected to a Fellowship at Trinity College, and Mr. A. Hutcheson of Christ's has been elected to a Fellowship at Pembroke College, in each case for distinction in Chemistry. Both gentlemen took first classes in each part of the Natural Sciences Tripos.

Mr. J. Y. Buchanan, F.R.S., University Lecturer in Geography will deliver a course of lectures on Oceanography during the present Term in the New Museums, on Tuesdays at 12 o'clock, commencing on Tuesday, October 18.

Mr. W. C. D. Whetham, B.A., Fellow of Trinity College, has been appointed Assistant Demonstrator of Physics in the Cavendish Laboratory.

Mr. W. B. Hardy, M.A., Junior Demonstrator of Physiology, has been elected to a Drosler Fellowship in Gonville and Caius College.

A claim of priority advanced by Mr E Cohn over M Bouty (see *Wiedemann's Annalen*, vol xxviii p 454).—Comparative evaporation of the solutions of sodium chloride, potassium chloride, and of pure water, by M Pierre Lesage. Within the limits of the experiments, pure water evaporates more rapidly than solutions of either chloride. The solutions of KCl have, with the same degree of concentration, a greater rate of evaporation than those of NaCl.—On a fossil piece of wood containing fluorine, by M T L Philpson. This was found in the cretaceous sandstone of the Isle of Wight, and analysed thirty years ago. It yielded 32.45 per cent of phosphoric acid and 3.90 per cent of fluorine. It had a brown colour and a density of 2.71.—Identity of cascarine and rhamnoxanthine, by the same.—On a respiratory globuline contained in the blood of the chitons, by M. A B Griffiths. The yellow blood of the chitons contains a respiratory globuline which contains no metal. It is colourless, and possesses the same properties of oxygenation and deoxygenation as hemoglobine, chlorocruorine, and other respiratory substances. Its empirical formula is

It has been named  $\beta$ -achroglubine, to distinguish it from that of the *Pistella*, which has been called acroglubine.—Influence of the electric light on the structure of herbaceous plants, by M Gaston Bonnier. After his researches on rees carried out at the electric station of the Paris Central Markets, the writer experimented upon herbaceous plants under similar conditions. The plants were placed at distances varying from 15 to 4m from arc lamps, whose light was kept constant for seven months. The excess of ultraviolet radiation was intercepted by glass shades. Under these circumstances, the majority of plants exhibited intense activity of assimilation. 12 gr. of leaves of *Ranunculus bolbosus* developed 1.05 of oxygen in one hour, the corresponding figure for diffused daylight being 0.52, and for full sunlight in midsummer 3.95. A certain proportion of plants died off, even in intermittent light, especially if no shade was used. Some plants showed an exuberant vegetation, the leaves a deeper green, and the petals more striking colours. Of these, however, the larger number soon began to suffer from excessive assimilation. Some were able to adapt themselves completely, such as bulb plants, grasses raised from seeds, arborescent species, and submerged aquatic plants. The latter also showed no difference in structure, whereas the leaves of crocuses, anemones, and ranunculi became almost unrecognisable owing to anatomical modifications. As a general result, if the continuous electric light through glass produces a great development in an herbaceous plant accompanied by an intense green, the structure of the organs is at first highly differentiated; but if the electric light is intense, and prolonged for several months without change, the new organs formed by the plant, which are able to adapt themselves to this kind of illumination, present remarkable modifications of structure in their various tissues, and are less differentiated, although always rich in chlorophyll. Further, the direct electric light is prejudicial to the normal development of the tissues in virtue of its ultra-violet rays, even at a distance of more than 3m.

## FRESNEL'S THEORY OF DOUBLE REFRACTION

*The Optical Indicatrix and the Transmission of Light in Crystals* By L. Fletcher (Oxford University Press Warehouse, 1892)

MR FLETCHER has given us a valuable and most interesting book. He has attacked some parts of the theory of double refraction in a manner which is free from many of the objections that may be made to the method more usually adopted, and which has the advantage of closely resembling that by which Fresnel himself made his great discovery.

In dealing with this discovery we must carefully bear in mind two facts. The result of Fresnel's theory—the determination of the actual form of the wave-surface in a biaxial crystal—is undoubtedly true, the mechanical reasoning on which, in his second memoir on double refraction, he bases that result, is as undoubtedly false. In recent times the explanation of the properties of the wave-surface has been usually based on the erroneous mechanical reasoning. Mr Fletcher, following Fresnel himself, has shown us how all these properties may be deduced from certain experimental results without the introduction of the false mechanics. In one sense this is a backward step, but since the advance had been in the wrong direction, it was necessary to retreat, and though Mr Fletcher's book teaches us nothing new of the mechanism of double refraction, it puts the kinematics of the theory and the geometrical results which it entails on a sure foundation, and this is an achievement for which the author deserves our warmest thanks.

The history of the discovery of the law of double refraction, as given in Fresnel's own papers, is of the deepest interest. The form of the wave surface, in a uniaxial crystal, a sphere and spheroid, had been discovered by Huyghens. Up to the time at which Fresnel wrote it was generally supposed that even in a biaxial crystal one ray obeyed the ordinary law of refraction. In 1816 Fresnel and Arago proved that in an isotropic medium the direction of the periodic disturbance to which light is due is transverse to the ray, and from that time Fresnel set himself to investigate the laws of double refraction. He soon saw that the reasoning which led him to expect that in a uniaxial crystal the velocity of one wave must be constant could not apply to crystals with two optic axes, and that in such, contrary to the usual belief, there could be no ordinary ray. This was announced in June 1820. The first memoir on double refraction, presented to the Academy November 19, 1821, but not printed till 1868, gives a detailed account of the experiments by which this result of his theory was verified, and contains the earliest development of the theory itself. According to Fresnel's views at this time the ether displacement in a crystal was at right angles to the ray—it is noteworthy that the latest development of the mechanical theory leads to this same result—and the velocity of propagation depended on the elasticity of the medium in the direction of displacement. Since, then, for any ray there are two pos-

sible velocities there must for that ray be two and only two directions of displacement, the light must be polarized in one of two directions. Since, also, the velocities are different in different directions, in Fresnel's view the elasticity corresponding to a given direction of vibration must depend on the direction, and a surface of elasticity can be drawn each radius of which shall be proportional to the elasticity in its own direction. When once this surface is known, the rest of the problem can be readily solved. Now, in the memoir we are referring to ("Premier Mémoire sur la Double Réfraction, Œuvres Complètes d'Augustin Fresnel," T II No xxxviii) Fresnel proved, for the case in which the double refraction was not strong, for which therefore the distinction between the ray and the wave normal might be neglected, that if for a uniaxial crystal the surface of elasticity were a spheroid of revolution the wave surface and the laws of double refraction would be those discovered by Huyghens. It was an easy step from this to generalize and to suppose that in a biaxial crystal the surface of elasticity might be an ellipsoid, and to examine the results. This gave him at once, to the same degree of approximation as in the previous case, the form of the wave surface known by his name and the experimental laws of biaxial refraction discovered by Brewster and by Biot. As yet the result was only approximate, worked out more completely the theory can be shown to lead to the same form of the wave surface as that developed by Lord Rayleigh (*Phil. Mag.*, June, 1871). Huyghens' laws and those of Biot and Brewster are not accurately obeyed.

But Fresnel's mind moved rapidly, and a week later, November 26, 1821 ("Extrait d'un Mémoire sur la Double Réfraction," Œuvres, Vol II, No xxxix), he corrected his first results and announced his complete theory. The modifications required were not great, in his original theory he had supposed the displacement to be at right angles to the ray, in the final form it is supposed to be at right angles to the wave normal, *i.e.*, in the wave front, while the elasticity in any given direction, and therefore the corresponding velocity, is given by the reciprocal of the radius vector of a certain ellipsoid instead of by the radius vector itself. With these modifications the wave surface is accurately Fresnel's surface and the experimental laws of double refraction are accurately obeyed. To this ellipsoid (of which the inverse is Fresnel's surface of elasticity) Mr Fletcher has given the name of the "Indicatrix." According to Fresnel's theory the two possible velocities of wave propagation in any direction are the reciprocals of the axes of the section of the indicatrix by the wave front. This law has been verified to a high degree of accuracy by direct measurement, and is thus made by Mr. Fletcher the basis of his treatment of the problem. These Memoirs of Fresnel's remained unpublished till 1868. The only printed announcement of the results was a notice in the *Moniteur*, December 12, 1821, with a view of claiming priority for the discovery, and the Report of the Referees, Fourier, Ampère, and Arago, who (August 19, 1822) recommended that it should be printed in full in the "Recueil des Savants Etrangers."

Instead, however, the Second Memoir on Double Refraction (Œuvres, tome II, No. xlvii) was printed

(tome vii of the *Recueil*) in 1827, the year of his death, and this is the paper which contains Fresnel's latest developments of his theory. In it he suppresses entirely his method of generalization and develops that mechanical theory by which, to quote his biographer Verdet, "he endeavoured to rediscover truths which a profound intuition had first revealed to him." The truths remain, and though Fresnel's methods and their historical development are clearly given in his collected works and in M. Verdet's most admirable introduction to them, Mr Fletcher has done good service to science in calling fresh attention to these earlier papers and in making a modification of this method of Fresnel's the foundation of his work.

In his note to the first memoir, when discussing the inexact reasoning by which Fresnel afterwards supported his mechanical theory, Verdet writes (*Ouvres de Fresnel*, ii, p. 327) —

"Il pouvait sembler singulier que le résultat définitif d'un raisonnement incomplet et inexact en deux points fût une des lois de la nature dont l'expérience a le mieux confirmé la vérité. On a vu au contraire que cette loi s'était manifestée à Fresnel comme le résultat d'une généralisation toute semblable aux généralisations qui ont amené la plupart des grandes découvertes. Lors qu'il a voulu ensuite se rendre compte de la loi par une théorie mécanique il n'est pas étonnant qu'il ait, peut-être à son insu, conduit cette théorie vers le but qu'il connaissait d'avance et qu'il ait été déterminé dans le choix des hypothèses auxiliaires moins par leur vraisemblance intrinsèque que par leur accord avec ce qu'il était en droit de considérer comme la vérité."

True though this may be, the fact remains that until Lord Kelvin developed his theory of a contractile ether a few years ago, no one of the distinguished men who have followed in Fresnel's steps had discovered a satisfactory mechanical basis for Fresnel's great generalization. But to return to the book before us. As has been mentioned, Mr Fletcher's method of development differs somewhat from that indicated by Fresnel. He finds it more convenient to work with rays than with wave-normals or wave-fronts, and the construction he adopts is the following — Draw a normal at any point of the ellipsoid of elasticity — the indicatrix in Mr Fletcher's language. From the centre of the ellipsoid draw a line perpendicular to this normal, and consider a ray travelling in the direction of this perpendicular. Then the reciprocal of the intercept on the normal between the surface and the ray measures the velocity of propagation along the ray, and the plane of polarization of the ray touches the indicatrix at the point at which the normal is drawn. According to Fresnel's theory the radius vector drawn from the centre to this point is the direction of vibration in the ray, while according to the most recent modification of the theory, the motion takes place along the normal itself. From this simple construction the form of the wave-surface and all the known laws of the propagation of light in crystals are deduced in a strict and skilful manner. At the same time, while giving Mr Fletcher the fullest credit for his originality, we are at times inclined to wish he had adhered more closely to Fresnel's method. He admits of course himself that a single ray cannot be propagated through the ether. We may hope that some of those who read his book will go on to study

the mechanical theory of double refraction. Then they must deal with waves and not with rays, and they would find it an advantage to have had the one idea to guide them throughout. Again, the new method leads to a multiplicity of names for one and the same thing, and this is a disadvantage. We have ray-surface used for wave-surface, although the two are identical, nor is it easy at first to recognize the optic bi-normals and the optic bi-radials as the optic axes and the lines of single ray velocity respectively, but these are small points when compared with the main object of the book, which well deserves attention and careful study. The last chapter deals with the problem in a more general way, but space forbids us to follow Mr Fletcher into the questions he there raises, it must suffice to call the reader's attention to it, and especially to the fallacy discussed in Section 17.

R I G

### THE PROGRESS OF HORTICULTURE

*Contributions to Horticultural Literature*. By William Paul, F.L.S. (Waltham Cross, Herts. W. Paul and Son, 1892.)

FOR about half a century Mr Paul has been labouring at the work of horticulture alike in the garden and at the desk. As a business man he has not confined himself simply to commercial routine. As an observer and an experimenter he has not been hedged in by the dogmas and prejudices of any particular school of science, and as a writer his aim has always been to record truthfully and instruct faithfully. It is a matter of congratulation, therefore, that the author should have gathered together in a convenient form some records of a lifetime's work.

Certain portions we should have eliminated as of past or of personal interest only, certain others as of relatively minor importance, but Mr Paul is addressing a mixed audience with varied sympathies and interests, and it may be that the paragraphs we should mark for deletion would be those which others would best care to preserve.

Mr Paul groups his writings, as here collected, under the three heads of (1) roses, (2) trees and plants, and (3) fruit culture and miscellanea. They would fall equally well under other categories, such as the commercial and practical, the æsthetic and the biological. In this notice we must confine ourselves to Mr Paul's writings as a naturalist. Such, however, is the interdependence among various branches of inquiry, that it is almost impossible, in this connection to isolate any special subject, even if it were desirable to do so. From this point of view Mr Paul's book is, though undesignedly, an apt representation of the present condition of horticulture. On the one hand, the relations of that art to the perception of and to the canons of beauty are obvious. Equally clear are its bearings on routine practice. On the other hand, its connection with biological science, in spite of the teaching and example of Darwin, is not yet adequately recognized, nor has the statesman as yet grasped the truth that progress in agriculture must follow to a large extent on the lines familiar to horticulturists. Of the many remedies proposed to mitigate and clear away the depression under which agriculture is suffering, none is more likely to be serviceable than the adoption, so far as

circumstances permit, of the principles and practice of the progressive gardener. This is very obvious to those conversant with the state of commercial horticulture, as contrasted with the condition of the corresponding department of agriculture, and it will be brought home to the thoughtful reader by the perusal of some of Mr Paul's pages. It is interesting, too, to see that matters at which some minds would still be inclined to scoff as unpractical, or which they would regard as mere means of affording agreeable recreation, are the very departments in which the greatest practical successes have been achieved in the past, and which are of the best augury for progress in the future.

Biologically speaking, Mr Paul has been not only a keen observer but a careful experimenter on a very large scale, and over a very long period. It is true his experiments have not been and could not have been made with the exact accuracy which we expect in the laboratory, but they have been made under conditions far more akin to those which occur in nature. Moreover, they have been made, although with a definite aim, yet without reference to any particular theory. The reader will accordingly find in these pages records of work and inferences from carefully planned experiments directly bearing on many subjects now attracting the attention of naturalists, such as hereditary transmission, variation from seed or from bud, selection, fixation, close fertilization, and the various degrees of cross-impregnation. Incidentally these subjects receive illustration in many chapters of Mr Paul's book, but the address on "The Improvement of Plants," which was read in 1869 before the provincial meeting of the Royal Horticultural Society at Manchester, contains a summary of Mr Paul's views on these subjects, which we strongly commend alike to the notice of naturalists and of agriculturists.

It is very interesting to compare what he says about selection and variation in plants, such as the *Camellia*, the Chinese Primrose, or the Hollyhock, which are the offspring of what we regard as pure species, with the corresponding processes in the Rose, the Pelargonium, or the Chrysanthemum, which are veritable mongrels. In this connection we may in passing allude to the power which the gardener has, of course within limitations, of creating new forms. The orchid cultivator, for example, inferred parentage of certain hybrids met with in a wild state, but he has since proved the correctness of his inference by actually producing in his orchid-house many of the same forms that occur in the forests of the tropics. Another very striking case (not specially alluded to by Mr Paul) is the production and development of what are known as tuberous *Begonias*. These have been evolved by the art and patience of the gardener within the last quarter of a century from repeated crossing between certain Andean species of *Begonia* and their descendants. The result is the establishment of a race so totally distinct from anything yet known in nature as would justify a systematic botanist in forming a separate genus for their reception. Many an accepted genus is based upon less important points of distinction than those which characterize the tuberous *Begonias*, and which, indeed, have been gathered together by Fournier under the genus *Lemoinea*. The degree of permanence of this artificially formed genus is, of course, unknown, but we

do know already that the peculiarities are reproduced from seed, and that each year the plants are, as the gardeners say, becoming more "fixed." We have alluded to these as illustrations of the kind of work upon which Mr Paul has been engaged for half a century. They may be taken as examples of the material he has gathered together in this book, which is not merely presented for the delectation of the ordinary lover of flowers or the profit of trading horticulturists, but is also calculated to increase the productive resources of the country, as well as to forward the progressive development of our knowledge of the natural history of plants.

As a further illustration of Mr Paul's method we cite in conclusion a passage which will, we think, justify us for recommending to scientific readers the perusal of a book which they might be disposed, from its title, to think had little in it to interest them. "My experience in selecting, hybridizing, and cross-breeding tells me that he who is seeking to improve any class of plants should watch narrowly and seize with alacrity any deviation from the fixed character, and the wider the deviation the greater are the chances of an important issue. However unpromising in appearance at the outset, he knows not what issues may be concealed in a variation, sport, hybrid, or cross-bred, or what the ground newly broken is capable of yielding under careful and assiduous cultivation. If we would succeed in this field we must observe, and think, and work. Observation and experiment are the only true sources of knowledge in nature and while observing and experimenting we should above all things guard against prejudices."

MAXWELL T. MASERS

#### LIFE IN MOTION

*Life in Motion or, Muscle and Nerve.* By John Gray McKendrick, M.D., F.R.S. (Adam and Charles Black, 1892.)

UNDER this title Prof McKendrick gives us the gist of six lectures delivered by him during last Christmas holidays to a juvenile audience at the Royal Institution of Great Britain, and, judging from this little work, it is evident that no pains was spared by him to render these lectures as instructive and interesting as abundant illustrations and experiments could make them. In presenting these lectures to the public in book form he places us under an obligation gratefully to be acknowledged for professional physiologists stand alone amongst their colleagues in other departments of science in their disdain of any attempt at the production of attractive and simple scientific literature. In very pleasing sympathetic style the reader is introduced to the world of motion and to the special motions of the living muscle. He is shown how the movements of a muscle are recorded by the physiologist, and the apparatus used for its stimulation. Artificial tetanus is described, the muscle sound and its elasticity referred to, and a perhaps too short description given of amœboid and ciliary motion. The physiology of the nerve is then discussed, and the production of heat in muscle. In the fifth lecture is a short account of the sources of muscular energy, a comparison is drawn between a muscle and the steam engine, and a comparatively detailed account of muscle fatigue is given.

The sixth and final lecture deals with the electrical phenomena of muscle and with a very curious group of fishes termed "electrical"

The arrangement of the book is excellent, yet we are inclined to think that it shares with many other works on physiology one common fault. What we all want to know more about is the life and activity of the organism, and the physiologist very rightly spends much of his time in experimenting in every conceivable way, and generally with isolated parts of the organism. His apparatus is often of the most varied and intricate kind, and his experiments yield him definite results. Many of these results, however, are at present of little value in shedding light on physiological processes, and should not, we think, obtain the prominent position they now occupy in the text-books. To take an example, the experiment to demonstrate the muscle curve, in which the muscle is isolated and stimulated electrically, is one of the stock experiments minutely described in every text book. In this experiment the muscle is separated from its antagonistic muscles, stimulated in quite an unnatural way, and the result of the experiment is totally different from what takes place in a contracting limb. It is certain that in nearly every text-book the reader will find that from this and similar experiments he is apt to obtain incorrect and misleading ideas. He no doubt learns something regarding very interesting electrical machinery, but very little physiology. Of recent years far more attention has been bestowed upon the movements of muscles in the limbs, and comparative physiology is at last asserting its influence. It is to be hoped that when this knowledge finds a more prominent place in text-book literature, "muscle and nerve physiology," in the proper sense of the term, will be more satisfactorily taught.

Returning to what more exclusively concerns Prof McKendrick's book, we may point out a slip on page 81, where it would appear that the muscle sound corresponds in pitch to the fundamental tone of a body vibrating 19.5 times a second, instead of to one vibrating at twice that rate, and that Prof McKendrick does not interpret this sound on the lines followed by Helmholtz and others. On page 91 the modern view of a "cell" is represented in a drawing, and the nucleus has inadvertently been omitted. On page 31 a long and short circuiting key is represented, while a simple key is described in the accompanying text. These, however, are but trivial faults to find in an excellent little work, which is most admirably got up and beautifully illustrated by nearly one hundred excellent figures.

The reader will, we think, obtain a good insight into a department of physiology, and will be stimulated to further research in the literature of this interesting subject.

J. B. H.

### PLUMBING

*Principles and Practice of Plumbing* By S. Stevens Hellyer (London: George Bell and Sons, 1891.)

THOSE who are acquainted with Mr Hellyer's larger book on domestic sanitation, "Dulce Domum," will not find much new matter in the present volume, but

the subjects are treated less discursively, and are fairly well brought down to date.

There is no trade which has been more discussed in recent years than that of plumbing, and if plumbers are not impressed with a sense of their responsibilities, it is certainly not the fault of the architects and engineers who employ them. The manual skill necessary to perform the most ordinary operations is in itself so difficult that many workmen fail to acquire it, and, on the other hand, many experts in the details of the craft are never properly educated in the principles of sanitation which are necessary to make their work effectual from a sanitary standpoint. It is the combination of both kinds of knowledge in the writer which makes Mr Hellyer's books of exceptional value. It matters little whether it is an architect on one hand, or a working plumber on the other, who studies them, because they are of equal value and of equal interest to both. The present handbook is specially valuable in these respects because most of the information upon matters of practical workmanship is given concurrently with the reasons which should control the details and the principles which should be in evidence when the work is finished.

No one unacquainted with the practical difficulties which frequently crop up in sanitary practice can realise how much knowledge and experience is necessary to overcome them. Houses in London often present the most puzzling problems, and an intimate acquaintance not only with the principles and practice of the subject, but also with all the most recent appliances, is required for their successful solution. The ventilation of all the different parts of a complicated drainage system, including that which is necessary to prevent the syphonage of traps, sometimes requires an amount of thought and attention which a layman would think was uncalled for in the face of its apparent simplicity. It is no wonder that there are frequently failures to meet the highest standard of excellence, especially when incompetent persons are employed to design and superintend the necessary operations. On the other hand, there are thousands of houses in London in which no such difficulties occur, and in which the drainage and plumbing arrangements ought not only to be extremely simple in themselves, but intelligible to the ordinary householder. When such cases are entrusted to a builder, or an intelligent plumber, the first requisite is the manual skill required to carry out the various details, and this must be acquired by the workman through apprenticeship, or from his having acted as the assistant or "mate" of a journeyman for several years. The next requisite is that he should have a clear knowledge of what he is going to do and why he does it. This may be acquired to a great extent from his being familiar, in his capacity as a workman, with the designs of an architect or engineer under whose directions he has been employed, and it is to such men that Mr Hellyer's text-book should be specially valuable. By studying its pages he will avoid many mistakes. He will know what sort of joint to make, what kind of trap to avoid, how to secure the traps from syphonage, and how generally to complete his work so as to pass the latest standards of excellence. We can equally recommend it as a text-book for architects.

who, although they are unable to acquire any technical skill in carrying out the operations themselves, should have, nevertheless, an intimate knowledge of the principles which they ought to embody

We think that more space should have been devoted to that portion of the book which deals with drainage proper. While nearly 100 pages are given to lead-laying and the jointing and bending of pipes, only about twenty pages are devoted to house drains, and a great part of this is occupied with illustrations of appliances. Not more than one or two pages are given to the subject of cast-iron drains, although they are strongly recommended, and the subject is a very important one. We trust, however, that the author will remedy these deficiencies in the future editions which will doubtless be required to supply the demand for his excellent text-book

### OUR BOOK SHELF

*A Lecture Course of Elementary Chemistry.* By H. T. Lilley, M.A. (London: Simpkin, Marshall, Hamilton, Kent and Co., 1892)

THE abrupt use of chemical terms, and the condensed style adopted by the author in this book, make it evident that it is not specially designed to smooth down the difficulties which confront the unaided learner who approaches chemistry for the first time. It seems rather to be fitted to replace the notes which might be taken on a course of lecture instruction. Regarded in this light it is a useful volume, the knowledge it contains being, in the main, sound and to the point.

It deals with the metals as well as with the non metals, and dovetailed with the ordinary chemical information are many instances that the author has tried to keep pace with current work, and has attempted to give the student all the important points to be noted in a fairly complete course of elementary chemistry.

A short series of exercises chiefly in chemical arithmetic are given at the end of the book, and a table of contents and an index are supplied.

It would be advisable on p. 53 to say that ordinary sulphur crystallises in the rhombic system. To speak of the crystalline form as an octohedron tends to create an impression common among students, that ordinary sulphur belongs to the cubic system. Fluorine was not made by the electrolysis of liquefied hydrofluoric acid, but of a solution of potassium fluoride in the acid, the pure acid is a non-electrolyte.

It is hardly correct to state that calcium sulphate and hydroxide are the only known examples of solids less soluble in hot than in cold water, calcium isobutyrate and one of the thorium sulphates are additional instances. On p. 98 the flame colorations of potassium and sodium are confused, and brass seems to be omitted in treating of the alloys of copper and zinc.

J. W. R.

*Longmans' School Geography for North America.* By George C. Chisholm and C. H. Leete. (New York: Longmans, Green, and Co.)

IF Mr Chisholm's well-known geographical text-book was to be extensively used in the United States, it was inevitable that it should be altered in a way which would adapt it to the special needs of American schools. The task was undertaken by Mr Leete, and he has accomplished it with much skill and judgment. The parts he has rewritten are those relating to America in general, North America, and the United States. To these he gives a prominence which was not necessary or desirable for European students of geography, but which is no doubt essential for learners on the other side of the

Atlantic. The plan of Mr Chisholm's book and the spirit of its execution have both been maintained, and the work ought now to be quite as useful in the New World as it has already been in the Old.

*Garden Design and Architects' Gardens.* By W. Robinson, F.L.S. (London: John Murray, 1892)

THE author of this book is firmly convinced that to clip and align trees in order that they may "harmonise" with architecture is "barbarous, needless, and inartistic." He is in love with Nature's methods, and would give them in gardens much freer scope than is accorded to them by persons who like best a certain trimness and formality. It is to be regretted, perhaps, that Mr Robinson deals with the subject in so polemical a temper, but the cause for which he contends is good, and he does excellent service by bringing out prominently what has always been the essential principle of the best and most characteristic kind of English landscape gardening. The value of the essay is greatly increased by a number of well-selected illustrations.

### LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

#### The Alleged "Aggressive Mimicry" of *Volucella*

IN the course of a review (NATURE, October 6, 1892, p. 535) of a book, "Animal Coloration," by Mr Beddard, Mr Poulton takes occasion to refer to a theory professing to elucidate the resemblance of *Volucella* to humble bees, &c. This reference is occasioned by the suggestion of a counter-hypothesis by Mr Beddard. The view adopted by Mr Poulton ("Colours of Animals," 1890, p. 267) is that proposed by Kirby and Spence, and subsequently alluded to by Kunckel d'Herculais ("Organ et Dével des Volucelles," Paris, 1875) and others, but as Mr Poulton makes no reference to these authorities he may be assumed to accept the full responsibility. In the place named he says—"The boldness of these enemies sometimes depends on the perfection of their disguise. Thus the larvae of flies of the genus *Volucella* live upon the larvae of bees and wasps. *Volucella bombylans* occurs in two varieties, which prey upon the humble bees *Bombus muscorum* and *B. lapidarius*, and are respectively like these Hymenoptera. The resemblance is very perfect, and the flies enter the nests to lay their eggs." Mr Beddard (l.c., p. 225) criticizes the view that the fly resembles the bee that it may with impunity enter the nest, and proposes to look on the presence of the fly's larvae in the bees' nests as akin to the presence of supposed "pets" in the nests of ants. As Poulton points out, this suggestion leaves the original difficulty of the likeness of the fly to the bee untouched.

Having little interest in either of these speculations, which seem fantastic and premature, it is with reluctance that I take part in the discussion. The case, however, of *V. bombylans* is not only interesting as a striking, and to us in England a most accessible instance of the phenomenon of Mimicry, but as an example of Variation it is almost unique among animals, while among plants perhaps it is paralleled only by Darwin's famous case of the peach and the nectarine. It is besides a case well suited for experiment and close observation. The nests of surface building bees may towards evening be lifted bodily, bees, *Volucella*, and all, with a spit of earth, and transferred to a box. This may be taken home and set next morning on a window sill, when on opening the box the bees will go on with their work for the rest of the summer. If any one seeks an opportunity of honestly trying to get to the bottom of a case of Mimicry, instead of speculating about it at large, he can scarcely find a better case than this. The need for such observations is great, for the account confidently given by Poulton, though according well with his hypotheses, accords with the truth less well.

In these circumstances it may not be out of place to give a brief statement of the facts as they were established by entomologists long ago. The *Volucella* are a small group of flies, con-

taining four British species (Verrall, "Cat Brit Dipt," 1888), of these most if not all resemble various Hymenoptera. The commonest and most remarkable is *V. bombylans*, which may be seen in any English hedgerow on a sunny day in early summer. This fly exhibits the rare condition of existing in two distinct forms in both sexes. The one form is black with a red-tail, in no small degree resembling a small worker of a red-tailed humble-bee such as *B. lapidarius* L. or *B. Deshamellus* Kirby. The other form has a yellow border to the thorax, yellow hairs on the antero-lateral parts of the abdomen, and a grey tail, to an equal degree resembling a small worker of one of the several yellow banded humble bees, e.g. *B. hortorum* L., *B. terrestris* L., or *B. Scrimshiranius* Kirby. Both varieties occur in both sexes and are about equally common. The problem of the evolution of these distinct forms is thus one of the most complex. Some may ask, If the varieties are thus distinct, how are they known to be one species? The evidence of this is (1) that no point of structure can be found to differentiate them, (2) that males of the one variety have been seen coupled with females of the other and *vice versa* (Macquart, "Suites à Buff," p. 479, Zeller, *Stet ent Ztg*, 1842, p. 66), and lastly (3) that intermediate forms have been found as rarities (Erichson, *Stet ent Ztg*, 1842, p. 115). This evidence may not satisfy all, but as regards Mr. Poulton the identity of the two as one species is not in dispute, for he admits this.

But though the likeness of *V. bombylans* L. and its var. *mystacea* L. (= *plumata* de Geer) to the red tailed humble bees and to the yellow banded humble-bees respectively, is really close, neither these forms nor the less common var. *hamorrhoidalis* Zt. present any special likeness to *B. muscorum* L., which has a bright brown thorax and a grey abdomen. It is true that Kunckel has spoken of a resemblance between the var. *mystacea* and *B. muscorum*, but it is hard to see upon what ground, for indeed it is much as if one were to liken a tabby cat to a fox. As Kunckel himself says, the great resemblance of the fly is to the yellow banded *B. hortorum*.

To return to Mr. Poulton's statement, he says that the two varieties prey upon "*Bombus muscorum* and *B. lapidarius*, and are respectively like these Hymenoptera." These words contain an ambiguity which I cannot believe intentional. But supposing for a moment that one of the varieties were like *B. muscorum* (which it is not), the sentence must be taken to mean that each variety preys upon the species of bee which it most resembles, the red-tailed variety on the red tailed bee and the yellow variety on the other. This is indeed demanded by the hypothesis of "Aggressive Mimicry." In this form the statement is often made, though I never met it elsewhere in print. I invite Mr. Poulton to produce observations in support of that statement. If he will establish it he will do a useful work. When this statement was written I must believe that Mr. Poulton had not read the several authorities on the subject, many of whom relate how both varieties have been reared from the nests of each type of bee, both from the red tailed and from the yellow-banded (Kunckel, p. 58, Drewsen, *Stet ent Ztg*, 1847, p. 211, F. Boie, Kroyer's "Naturh. Tids," 1838, p. 237). It is still possible that both varieties are born of one mother, and it is possible, too, that each female does her best to choose the nest of a bee like herself, but in support of this hypothesis I know no evidence, and indeed Kunckel (p. 58), after considering this possibility, gives it as his opinion that probably the varieties of *V. bombylans* lay indifferently in the nests of all *Bombi*. From the omission of these facts, which to an appreciation of the evidence are vital, we should infer that Mr. Poulton was not acquainted with Kunckel's work, were it not that he repeats Kunckel's selection of *B. muscorum* as a form resembled by one of the two varieties.

But though Mr. Poulton is wrong in saying that either variety specially resembles *B. muscorum*, he is right in saying that *V. bombylans* preys on this bee's nests, for both varieties have been bred from them, even from the same nest (Kunckel, p. 58). In my rooms at this moment are several nests of *B. muscorum*, each containing many larvae of *V. bombylans*, resting for the winter, to emerge in summer, as I hope.

There is then evidence that the two varieties, though they may breed together, yet remain substantially distinct, and that though they respectively resemble different species of bees, they are both found together, not only in nests of bees which they resemble, but also, and in my own experience, more abundantly, in the nests of another bee which they do not resemble.

Mr. Poulton further omits to mention that *V. pellucens*, though in nowise resembling the common wasp, yet lives in its nests, together with *V. thomis* which does resemble a wasp, and *V. sonaria* which is like a hornet (Kunckel, pp. 54 and 55). This fact also I commend to Mr. Poulton's ingenuity.

The publication of statements like this of Mr. Poulton's, omitting most salient facts—facts, besides, which, though adverse to his speculations, add a ten fold interest to the subject—is surely unfortunate. It may be replied that Mr. Poulton's book is of a popular character and does not aim at the completeness of scientific work, but in making choice of evidence, even for popular exposition, it is well to remember that the value of facts is not to be measured by the ease with which they may be momentarily fitted to the sustenance of a facile hypothesis.

WILLIAM BATESON

St. John's College, Cambridge, October 9

### Induction and Deduction

MISS JONES agitates a question that ought not to settle down without having caused that discussion which its propounding is fit to awaken.

This discussion does not, however, relate to the mutual relations of Induction and Deduction—at least, not as the main topic thereof. It relates to the fragmentary condition of that which is usually referred to and accepted as logic. We are so apt to take it for granted that our so called logic is tolerably competent and complete as an account of human reasoning in general, that it is of great utility when some one—as Miss Jones does now—raises a question that is adapted to direct our reflections towards some one of the several, perhaps many, gaps that exist in that most important, but too often not understood and misunderstood, branch of science. It is with this specially in view that I have ventured to write this.

In geometry nothing is more usual than to draw a universal conclusion from a case that, to all ordinary ways of apprehension, seems to be a single instance. Indeed, this is one of the cardinal features of geometrical reasoning. Perhaps we might well say that it is the most characteristic feature. It is this feature that the question that Miss Jones agitates ought to call into prominent notice.

She selects for her purpose the case of the isosceles triangle, and asks, How, from premising that the angles at the base of an (one) isosceles triangle are equal to each other, are we logically warranted in concluding that that same equality is true of all isosceles triangles?

That we do thus conclude is known to all, as is also the truth that such a conclusion is a typical one in geometry. Nor have we, nor can we have, the least misgiving as to the rigorous validity of such conclusions.

It would be a digression for me to point out here the essential characteristics of that form of reasoning which, properly speaking, is induction. It is sufficient for my present purpose to remark that true induction is utterly unable to yield us any conclusion that is more than *probable and approximate*.

From these characteristics alone we may know that our geometrical conclusions in view are *not*, as Miss Jones takes them to be, inductive conclusions.

But since our geometrical conclusions are natural and valid, the question still remains, What sort of conclusions are they?

If we propose to call them deductive conclusions, then, when we revert to the array of syllogisms, categorical, hypothetical, disjunctive, dilemmatic, &c., we find none of them, nor any combination of them, that can by any means be made applicable. We have to get not merely from an apparently particular but from an apparently absolutely singular proposition to a universal one. To do this deductively, the body of doctrines and canons, that is usually called logic, confesses itself wholly unable. It lays down as one of its cardinal rules, one that it declares is "founded upon the Laws of Thought," that if any premise is particular, then only a particular conclusion can be drawn.

Nevertheless, I am going to submit that the reasoning under discussion is a true instance, not of induction, but of deduction. I submit that the reasoning that we do actually follow is that which may be formulated thus—

*This isosceles triangle is ANY isosceles triangle*

*The angles at the base of this isosceles triangle are equal to*

each other. Therefore, the angles at the base of any (or every or all) isosceles triangle are equal to each other.

In order to make the nature of this reasoning plainer, I will put the same in symbols.

Put  $X$  = the isosceles triangle in general,  
 $Z$  = this particular isosceles triangle,  
 $a$  = angles at the base,  
 $e$  = equal to each other.

Then our reasoning will appear thus—

$Z$  is  $X$ ,  
 $a$  of  $Z$  is  $e$   
 $a$  of  $X$  is  $e$

This looks very much as though we had in hand a case of the logic of relatives.

We will all recollect the challenge of De Morgan—"If any one will by ordinary syllogism prove that because every man is an animal, therefore every head of a man is a head of an animal, I shall be ready—to set him another question." This would be in symbols—

All  $M$  is  $A$ ,  
 $h$  of  $M$  is  $h$  of  $A$

Our case, according to this sort of formulation, would appear—

$Z$  is any  $X$ ,  
 $a$  of  $Z$  is  $a$  of  $X$ ,  
 $a$  of  $Z$  is  $e$ ,  
 $a$  of  $X$  is  $e$

The distinguishing characteristic of our case as compared with the case put by De Morgan resides in the different natures of the two propositions—

All  $M$  is  $A$ ,  
 $Z$  is any  $X$   
 and

The former is the usual universal categorical affirmative proposition of ordinary logic. The latter is a sort of universal categorical affirmative proposition that certainly exists and is important, but which has not yet been recognized, unless it may be by the quantifiers of the predicate in their proposition—

All  $A$  is all  $B$

It implies rigorously that not only

$Z$  is any  $X$ ,  
 $Z$  is every  $X$ ,  
 $Z$  is all  $X$ ,

but that

any (or every or all)  $X$  is  $Z$   
 " ( " " ) not  $X$  is not  $Z$   
 " ( " " ) "  $Z$  "  $X$   
 any  $X$  is every  $Z$   
 every  $X$  is any  $Z$   
 every not  $X$  is any not  $Z$   
 any " &c. &c. "

In truth, to a superficial notice, it may easily seem to confuse the most important logical distinctions. But this is only because we are so used to identifying logic in general with the logic of extension. It is the logic of extension, or in other words, metric logic, that has been persistently tendered to us as the only logic worthy of study, if not indeed as the only logic practicable or perhaps possible. Yet we can now, I think, see that geometry at least makes great use of a logic that is not the logic of extension, and that the existence of geometry is an earnest that that other logic may be developed and formulated, if not completely at least to some very useful extent.

The proposition,

$Z$  is any  $X$ ,

is, as I conceive, a proposition of the logic of intension. It applies not to things, or to concepts in connection with things, but to pure abstract concepts like geometrical figures, whose marks are exhaustively specified, or, if any are not specified, the same depend upon and are implied by those that are specified.

One point more remains to be explained.

We must not from the recognition that  $Z$  is any  $X$ , and the rigorously following proposition that whatever is true of either  $X$  or  $Z$  is true of the other, conclude that these propositions should if valid hold for marks that are accidental to  $Z$ , or to any single instance of  $X$ . If we fail to keep clearly in mind the intensive scope of our propositions, we may discredit them, or

one of them, by observing that although we have laid down that whatever is true of  $Z$  is true of any  $X$ , yet nevertheless it does not follow that  $Z$  is any  $X$ , as regards say the size of  $Z$  or any single instance of  $X$ . Size may not be any necessary mark of either, and if so it is for all logical purposes impertinent to the propositions in question, and must be altogether ignored.

I will conclude by saying that the inference actually made in the case put by Miss Jones is a deduction, because it necessarily follows from the premises laid down. Logic has no connection with the truth of premises; it only says what certain propositions entail. If in an intensive sense this isosceles triangle is any isosceles triangle, then any isosceles triangle is this isosceles triangle, and every isosceles triangle is this isosceles triangle, and all isosceles triangles are this isosceles triangle, and if the angles at the base of this isosceles triangle are equal to each other, it follows necessarily that the angles at the base of all isosceles triangles are equal to each other.

Chicago, August 16

FRANCIS C. RUSSELL

BY the courtesy of the Editor of NATURE I have been allowed to read Mr. Francis C. Russell's very interesting remarks with reference to my note on "Induction and Deduction" in NATURE of July 28 (p. 293).

I agree with Mr. Russell as to the validity and certainty of an inference from equality of angles in *one* isosceles triangle to equality of angles in *all* isosceles triangles. But while I regard this inference as a "true induction" because it is an inference to a general proposition on the strength of a particular instance, Mr. Russell denies that it is an induction because he holds that induction can give only approximate and probable conclusions, and considers that the certainty which he allows to belong to the geometrical conclusion in question is due to the fact that the inference is *not* from a particular instance, but is really and truly *from universal to universal*—the one isosceles triangle from which the argument starts being a kind of "pure abstract concept," so that we can say—

*This one isosceles triangle is any isosceles triangle, therefore every isosceles triangle is this isosceles triangle, &c.*

This appears to me to be entirely inadmissible. How can *this triangle BE that and the other triangle?* To say that it is, is to lose sight of the distinction between *identity of individuals*, and *similarity of characteristics*. And that the assertion (*this triangle is every triangle*) is untenable appears also from Mr. Russell's own admission further on, when he says that "we must not, from the recognition that  $Z$  is any  $X$ , and the rigorously following proposition, that *whatever* is true of  $X$  or  $Z$  is true of the other, conclude that these propositions should, if valid, hold for marks that are accidental to  $Z$  or to any single instance of  $X$ ." If  $Z$  is any  $X$ , how can any  $X$  have marks which  $Z$  has not, or  $Z$  have marks which any  $X$  has not? We cannot get out of the difficulty by reference to extension and intension, for this reason, that every categorical proposition, to be significant, must be read both in "intension" and in "extension"—that is, affirmatives must be understood as asserting identity of extension (application) in diversity of intension (signification), while negatives *deny* identity. "This isosceles triangle is *any* isosceles triangle" can have a useful signification only if it is interpreted to mean—

This triangle [not *is* but] *is similar* (in so far as isosceles) to any isosceles triangle—that is, all are *similar* in respect of the characteristics which are inseparable from equality of sides. Hence (as I said in my letter, July 28) "in all cases equality of angles at the base is inseparable from equality of sides."

I am not clear what precise meaning can be attached to the expression "pure abstract concept," still less how a geometrical figure can be an abstract concept. I am, moreover, disappointed that Mr. Russell makes no examination whatever of my own attempt to formulate the process from Particular to General.

With reference to Mr. Russell's symbolical argument—

$Z$  is  $X$ ,  
 $a$  of  $Z$  is  $e$ ,  
 $a$  of  $X$  is  $e$ ,

I think that it may be logically described as a process either (1) of Substitution (Jevons)—a kind of Immediate Inference dependent on identity of application—thus—

$Z$  is  $X$ ;

$X$  may be substituted for  $Z$ .

In  $a$  of  $Z$  is  $e$   
 substitute  $X$  for  $Z$ ,  
 and we have  $a$  of  $X$  is  $e$

Or (2) a combination of what Jevons calls Immediate Inference by Complex Conception (which I should like to class with some other Immediate Inferences as Extraversion, which is largely used in mathematics) and Mediate Inference, thus—

$Z$  is  $X$  (a)  
 $a$  of  $Z$  is  $a$  of  $X$  (b)  
 But  $a$  of  $Z$  is  $e$  (c)  
 $a$  of  $X$  is  $e$  (d)

(b) is Inference by Complex Conception from (a), (b) and (c) are the premises which give (d) as their (syllogistic) conclusion  
 Cambridge, October 11 L. E. CONSTANCE JONES

### The Temperature of the Human Body

MR CUMMING's second or "physical" query will, I think, require no answer if his first or "physiological" question is replied to. If an isolated muscle from which evaporation was prevented could go on working in a heat enclosure, and always remain at a lower temperature than the enclosure (which it could only do by transferring heat from itself to its surroundings), we should have to ask in good earnest how this was consistent with the Second Law of Thermodynamics. We are quite certain, however, that the temperature of the working muscle would always, when a steady state of things had been reached, be above that of the enclosure.

The temperature of an isolated muscle during activity (assuming that it could be kept alive and evaporation prevented) would, of course, not only be very much higher "at the equator" than "at the pole," but also somewhat above that of the surrounding bodies in either latitude. The intact homoiothermal animal, even when the temperature of the air is greater than that of its blood, is on the whole, within the limits which can be borne, always losing more heat to its surroundings than it receives from them. For heat is still becoming latent at the evaporating surfaces of the body, the skin and the respiratory mucous membrane, even when the balance of gain and loss by radiation, &c., is telling the other way, and, indeed, in general more evaporation than usual is going on when this is the case. The temperature of these surfaces is always kept below that of the blood which comes to them. The blood, therefore, always loses heat here, and gains it from the muscles, which accordingly transfer heat to a medium colder than themselves, even when the external temperature is higher than that of either.

If, of two similar and similarly situated men, A and B (I ask pardon for degrading an austere geometrical phrase to such loose and vulgar application), exposed to the same high temperature (above that of the blood, say), A sweats little and B much, while the blood-temperature of both remains constant, A must either produce less heat than B or lose more in other ways than evaporation of sweat. He may produce less either because he works less than B, or because even at rest his metabolism is not so active. Or an extra loss of water-vapour from the lungs may make up for the diminished loss from the skin. For example, in the dog, which has but few sweat-glands, nearly the whole of the evaporation takes place in the respiratory tract. Of course much water is evaporated from the skin which never appears as visible sweat, and it is possible that some persons give off a greater proportion of the total perspiration in this way than others do, the quiet steady sweater, if one may be allowed the expression, getting through as much work on the whole as the steaming paroxysmal kind of fellow who breaks out into dewdrops on the smallest provocation. But it should be clearly recognized that an air temperature equal to or above that of the blood is occasional, and not permanent in any latitude, and that men, and even animals, adopt expedients to avoid such extremes and to tide them over.

Any good recent text-book of physiology will give the information asked for as to what is known of the mechanism by which the temperature of warm-blooded animals is kept approximately constant. It is too wide a subject to be entered into here. In man the regulation of the heat loss seems to be far more important than any regulation of the production of heat. The former is, of course, largely voluntary, but the quantity of blood going through the skin, an important factor in more than

one way, is greatly influenced by reflex nervous impulses. It is doubtful whether the very considerable heat capacity of the bodies of large animals has been sufficiently taken into account in its bearing on the steadiness of the blood temperature. This in itself prevents any sudden change. In some animals, and apparently more especially in small animals—e.g., the rabbit and guinea pig—the production of heat, as well as the loss, is very distinctly under the control of the nervous system, and is increased when the external temperature is lowered, and diminished when it is raised.

Of course, as your correspondent is doubtless aware, we do not really know what kind of a machine a muscle is, except that it is a machine by means of which the potential energy of the food is partly transformed into mechanical work and to a much greater extent into heat. Up to a certain limit the work and the heat increase together, although less heat is given off by an active muscle which is allowed on the whole to do external work than by the same muscle when it constantly undoes its own work.

G. N. STEWART

New Museum, Cambridge, October 11

THE following brief account of the working of the heat mechanism of the human body will, I hope, help to make clear to Mr Cumming the problems of which he seeks the explanation.

The temperature of a man at the equator is within a degree Centigrade the same as that in the arctic regions. This is because, in the first place, in the arctic regions the loss of heat from the body is very slight, and in the tropics it is very great, for (a) in the tropics more perspiration is secreted by the skin, and this, in consequence of the high temperature of the air, evaporates very quickly, and hence the body is kept cool. It is true, as Mr Cumming says, that in the tropics people may not be observed to perspire freely, but that is simply because as fast as the perspiration is secreted it is evaporated. It is what is called insensible perspiration. (b) More water is secreted by the bronchial mucous membranes in the tropics, and in consequence of the higher temperature of the air it, like the perspiration, evaporates very quickly. The excessive secretion of moisture by the body when the temperature of the air is high, is shown in a Turkish bath, and leads, in a bath of about two hours' duration, to a loss of weight amounting with some persons to three pounds, and to a great diminution in the quantity of urine secreted. (c) In the tropics the vessels of the skin are more widely dilated than in the arctic regions, hence there is more blood in it, and therefore heat is more readily radiated and conducted from the skin to the external atmosphere. (d) The specific heat of the body is very high, and so it cools very slowly in the arctic regions. Judging from some experiments I have made on animals, it is, at the usual temperature of the human body, well over 1.0. (e) The above facts are certain, but in addition, for all we know to the contrary, the skin may, under different conditions, have different radiating powers quite apart from the quantity of blood in it.

In the second place, although it has not been calorimetrically proved, it is very highly probable that in the arctic regions the quantity of heat produced by the body is much greater than in the tropics.

With regard to the second query of Mr Cumming, no doubt, as he says, the human body in the tropics must often be the coolest of surrounding objects, in this case it cannot lose anything by radiation or conduction, but it is kept cool by the rapid evaporation of perspiration (usually insensible) and fluid secreted by the bronchial mucous membrane. Whether or not a man in the tropics produces any heat under such circumstances has not been demonstrated, but probably, although the production of heat falls very low, it does not entirely cease.

W. HALE WHITE

### Photographic Dry Plates

I HAVE found great difficulty in obtaining fresh photographic dry plates of whatever maker, from dealers, who frequently pass off upon the purchasers packets of plates which have been in stock for a long time, and consequently unfit for use. It has therefore occurred to me that this trouble might be avoided by the makers filling every packet as issued by them, thus following the custom of the Platinotype Company with their tins of paper. By such a system the purchaser would be able to protect himself,

and many makers' plates would be found much more satisfactory

I shall esteem it a favour if you will allow this letter to appear in your journal. Enclosing my card, I subscribe myself,

PREVENTION

### INVITATION TO OBSERVE THE LUMINOUS NIGHT CLOUDS<sup>1</sup>

SINCE the year 1885 a very remarkable phenomenon has been noticed in the sky in our latitudes, which well deserves to excite the interest of astronomers and geophysicists. The following is the substance of what has so far become known regarding the so-called luminous night-clouds.

In the latitude of Berlin the phenomenon shows itself only during a comparatively short period of the year from May 23 to August 11. While in the first years it was seen pretty frequently even before midnight, it has, during the last four years, rarely appeared except after midnight. The phenomenon appears in the form of cirrus clouds, which come out bright on the twilight sky. This especially distinguishes them from the ordinary cirrus-clouds, which, with the depths of the sun in which the luminous clouds are seen at present, come out dark on the light twilight sky. The colour of the phenomenon is generally a bluish white, which becomes yellowish and reddish in close proximity to the horizon.

Often repeated photographs which have been taken simultaneously at various points in the neighbourhood of Berlin, show that the altitude of the luminous clouds is constant and exceedingly great—82 kilometres. In consequence of this great altitude, they receive light from the sun standing below the horizon, which makes them appear light on the twilight sky. They are visible only so long as the sun shines on them, as soon as the shadow of the earth passes over them they become invisible. As a rule they begin in the morning, shortly before twilight, and they disappear as soon as the sun stands higher than 8° to 10° below the horizon.

Of late years these clouds have been seldom seen. Within the period above stated, they occurred this year only about ten times, while in the first years they were very frequent. Their appearance is subject to great changes, while they frequently exist only in a few little luminous stripes or patches, at times they appear in greater accumulations and with a more intense light. Especially in the last days of the period, from August 2 until 6, their light seems to be considerable in our latitudes. Generally they are observed in the proximity of the horizon—over that part of it under which the sun is.

Frequent observations of the movements of the phenomena, which, after midnight, are always from the direction of N.E.  $\pm 40^\circ$ , render it probable that the movements are caused principally through the resisting medium of the mundane space. In accordance with this is the fact that in the half-year after its appearance in this country, the phenomenon has been observed repeatedly in the southern latitudes of 53° by the meteorological observer, Mr. Stubenrauch, in Punta Arenas, as well as several times by ship-captains.

Other observations confirm the assumption of an annual wandering of this kind. For instance, in Graham's town under 33° S lat the phenomenon was observed on October 27, 1890,<sup>2</sup> and in Haverford under 40° N lat, according to written information it was observed on May 17, 1892. These dates, taken in association with the time of the appearance in this country, directly indicate a wandering of the phenomenon from N to S and back.

The luminous night-clouds decrease year after year in respect to the frequency of their appearance as well as

to their extent and to their intensity of light. The phenomenon therefore will entirely disappear within a few years. It seems, however, that during the next two years observations will still be possible, which may give us information regarding several questions of extraordinary importance.

Measurements of the apparent altitude of the upper limits of the luminous clouds, mainly in the time in which the upper limit of the twilight-segment has the comparatively small altitude of, say, 1° to 10°, would be of great value. Such measurements will serve to decide the question whether the altitude of the clouds varies under different geographical latitudes, providing that the measurements always refer to such points as lie within the upper limits of the clouds, produced by the shadow of the earth.

During the last few years the whole twilight-segment has been comparatively seldom filled out by the luminous night-clouds, and it may therefore frequently remain doubtful whether the highest point of the phenomenon really lies in the limit of the earth shadow. In order to make sure that the measurements are adapted to their purpose, they must be repeated as often as possible in intervals of a few minutes. In the evening this limit is generally recognized by the fact that within it parts of the phenomenon disappear from above, while towards morning new parts always become visible within the limit upwards. The distance of the zenith of the upper limit of the luminous clouds in the vertical of the sun for the latitude of Berlin, presuming that the phenomenon stretches over the whole of the twilight-segment, may be seen from the following statement—

Depth of the sun below the horizon	Zenith distance of the upper most limit
12 0	80
12 5	83
13 0	85
13 5	86
14 0	87

Moreover, as by means of a telescope the upper limit of the phenomenon is generally seen a little higher than with the naked eye, it is desirable that the telescope should always be adjusted to the limit-line seen with the naked eye. A comparison of the appearance seen with the naked eye with the one seen through the telescope, will enable the observer to discover easily the line corresponding to the one seen with the naked eye. The exactitude of these measurements must be about 3' to 6', with respect to the azimuth and to the altitude, while the time should be exact within two to four seconds.

The employment of photographic apparatus is of advantage for the indication of the place, as well as of the movements, of the phenomenon. But only those kinds of apparatus are suitable in which the proportion of the diameter of the opening to the focal distance is at least 1/4 or greater. If the proportion is smaller, the duration of lighting will last too long, and consequently, on account of the quick changings of the phenomenon, the details will get lost. With an apparatus of which the proportion of the aperture-diameter to the focal distance is 1/3, the duration of lighting for the various depths of the sun below the horizon, on condition that the phenomenon is light in some degree, is as follows—

Depth of the Sun below the Horizon	Duration of Lighting
9	16
10	21
11	27
12	35
13	48
14	72
15	122

<sup>1</sup> Scientific journals are requested to reproduce this article.  
<sup>2</sup> Compare *Astr. Nachr.*, No. 3008.

Generally at the same time stars become visible on the photographic plate, through which, in association with the time of photographing, the direction of adjustment of the apparatus is ascertained (that is to say, the position of the axle of the apparatus is ascertained).

With regard to equatorial regions, it is of great importance that the exact time in which luminous night-clouds pass through them should be determined. According to the observations hitherto made, the passing through the equator may take place in the time between the beginning of September and the end of October, and the return between the beginning of March and the end of April. Under  $20^{\circ}$  S lat., the time of passing through will, in that case, be from the middle of September until the middle of November, and from the middle of February until the middle of April, and under  $20^{\circ}$  N lat. from about the middle of March until the middle of May, and from the middle of August until the middle of October. In consequence of the daily rotation of the earth round its axis together with the distinct movements of the earth, atmosphere, it may be that the passing through the equator does not take place in the simple manner here described. It does not seem to be unlikely that the periods are not limited as exactly as stated.

Moreover, it is probable that the luminous night-clouds consist of a gas which is condensed in consequence of the lower temperature prevailing in the altitude of 82 kilometres. On the question relating to the nature of this gas depend several other cosmical questions. For instance, with respect to the temperature of the air of the mundane space and the temperature of the atmosphere at the altitude of 82 kilometres, which will be answered through comparing experiments in the laboratory. For this reason, spectrographs of the sunlight at low altitudes of the sun, in the season in which the phenomenon of the luminous night clouds is seen, are of great value. Such spectrographs should be taken in the evening shortly before sunset, and in the morning shortly after sunrise.

It appears that in the northern regions of the earth, in about  $70^{\circ}$  latitude, in the period from the middle of June until the middle of July, an especially great accumulation of clouds takes place, which, however, on account of the sun standing constantly above the horizon during this period, will be hardly visible. It will, therefore, be of special advantage for these regions to take spectrographs of the sunlight at low positions of the sun.

These short remarks regarding the importance of the phenomenon with reference to cosmical problems may serve to show that the observations necessary for the exploration of the subject are well within the sphere of astronomers and geophysicists. There can be no doubt that the observations necessary for the solving of these questions are far beyond the capacity of a single institution. Those who take interest in the furtherance of the questions we have indicated are therefore requested to assist through one or other of the kinds of observation above noted in the investigation of the luminous night-clouds.<sup>1</sup>

### SOME OPTICAL ILLUSIONS<sup>2</sup>

A STRIKING illusion, first described by Zollner some thirty years ago, and usually called by his name, appears in Fig 1. Of the four main lines each

<sup>1</sup> A publication, "Die leuchtenden Nachtwolken," by O. Jesse, which may be expected within the next months, will contain details regarding the entire present position of these questions.

<sup>2</sup> Abstract of a paper on "A Study of Zollner's Figures and other Related Illusions," by Joseph Jastrow, Ph.D. (with the assistance of Helen West), being a part of "Studies from the Laboratory of Experimental Psychology of the University of Wisconsin" - *American Journal of Psychology*, vol. iv. No. 3.

adjoining pair seems to converge at one end, and to diverge at the other, whereas in reality the lines are all parallel. The first step in an explanation of the illusion would be the determination of its essential factors, of its various forms, and of some general principle embracing under one formula its several varieties. The next step would be to correlate this formulation with some recognized psychological principle. The generalization is found

FIG 1

in the statement, that the direction of the sides of an angle are deviated toward the direction of the angle, and may be illustrated by reference to Fig 2. In this figure the continuation of the left horizontal line seems to fall below the right horizontal line, and the continuation of the latter above the former, in reality the two are continuous. Similarly, if the continuations of the oblique lines be added, they will not seem continuous, but diver-

FIG 2

gent slightly to one side or the other. If now we call the direction of an angle the direction of the line that bisects it, then the deviation is what would result from a drawing up of the sides of the angle towards this central bisecting line, the left end of the left horizontal line would be drawn up, and the right end of the right horizontal line would be drawn down, and thus the two seem discontinuous. The same would happen, though to a less

FIG 3

degree, if either oblique line were omitted. There are many other ways of illustrating this fact. Instead of drawing the right line horizontal, we may incline its right end downwards slightly, and then it will seem continuous with the left horizontal line. We may apparently incline both lines so that they would converge towards a point between and below them, as in Fig 3 and the like. Two further points or corollaries should be noted (1) that the

larger the angle the greater the deviation. Similar figures with acute angles substituted for the obtuse ones would show a scarcely perceptible illusion. (2) When obtuse

FIG. 4

angles are combined with acute angles, the deviating effects of the former outweigh those of the latter. In Fig. 4 the effect of the angle ACD would be to make the

FIG. 5

FIG. 6

line AB if continued fall below EC, while the effect of BCD would be to make AB fall above EC, the former outweighs the latter, and the illusion appears as directed

FIG. 7

by the angle ACD. The angle BCE reinforces ACD, while ACE reinforces BCD. Angles greater than  $180^\circ$  do not come into consideration. When all the angles about a

FIG. 8

point are equal, i.e., are right angles, the illusion disappears. Figs. 5 and 6 furnish other illustrations of the same principles. In Fig. 5 the line  $a$  seems continuous with  $c$  while it is so with  $b$ , and this because the obtuse

angles formed by lines  $a$  and  $c$  with the vertical lines respectively, deviate the lines  $a$  and  $c$  towards the direction of the angles sufficiently to bring them in line with one another. Fig. 6 adds the further complication—explicable upon the same principles—that the line is deviated once in one direction and then in the reverse direction.

We have next to show that the illusion of deviation from

FIG. 9

parallelism is similar to that from continuity. If the right-hand portion of Fig. 3 be rotated through  $180^\circ$  and placed below the left-hand portion, we have Fig. 7, in which we observe a tendency for the two horizontal lines to diverge on the left and converge on the right, this is just what our dictum demands. To strengthen this illusion we add more oblique lines, and thus more angles, the obtuse

FIG. 10

angles in all cases outweighing the acute ones—Fig. 8. We have now only to draw two figures like Fig. 8, side by side, and draw the oblique lines across the vertical ones (thus keeping the figure compact) to obtain Fig. 11, with which we set out. The possibilities of illusion do not stop here—by drawing the oblique lines in one direction on

FIG. 11

one side, and in the other direction on the other side, we can deviate the two halves of the same pair of parallel lines in opposite directions, as is done in Fig. 9, while most striking of all is the elaborate design of Fig. 10, in which it is difficult to realize that the four main lines are all straight and parallel. If the page be viewed with one

eye, and held horizontal nearly on a level with the eye, the true relations will appear. Fig. 11 is valuable for its conclusive demonstration that the deviation is proportional to the angle, the increasing angles gradually bend the straight lines away from one another, and give them the gradual change of direction of curves. These and other forms of illusion are all included in the generalization that the sides of an angle are deviated towards the direction of that angle.<sup>1</sup>

The psychological principle with which this general-

FIG. 11.

ization may be correlated is the law of relativity. This law emphasizes the fact that a sense-impression is not the same when presented alone and when in connection with other related sense-impressions. We cannot judge the direction of lines independently of that of the angles whose sides they form. As a further illustration of this principle it may be shown that angles will affect the apparent lengths of lines as well as their apparent directions. If in Fig. 12 we compare the horizontal portion of the uppermost figure with that of the lowest, it is

FIG. 12.

almost impossible to believe that they are of equal length. The intermediate horizontal lines seem intermediate in length, and thus illustrate the fact that the apparent length of the horizontal lines is directly proportional to the size of the angles at their extremities. The illusion would persist if we converted these figures into truncated pyramids by adding a line parallel to the horizontal line, and would

<sup>1</sup> The reader is referred to the original paper for further illustration of this dictum, as well as for explanations of apparent exceptions and a discussion of the conditions affecting it.

then illustrate the fact that equal lines may be made to appear unequal by the effect of the areas whose contours they help to form. A converse effect is illustrated in Fig. 13. Here the upper figure seems larger than the lower, because its larger parallel side is brought into juxtaposition with the smaller parallel side of the lower figure. This illusion and others show especially well when cut out of paper and held against suitable backgrounds. As the figures are moved about one another the upper constantly becomes the larger. More than two figures may be used, and a variety of such contrasts may be formed.

The subject is by no means fully considered in these illustrations nor is the explanation offered as final or adequate. If it seems to direct investigation into fruitful paths its chief purpose will be accomplished.

### THE NEW SATELLITE OF JUPITER

THE new number of the *Astronomical Journal* contains Mr. Barnard's account of his discovery of this additional member of our system. We make the following extracts:—"Nothing of special importance was encountered until the night of September 9, when, in carefully examining the immediate region of the planet Jupiter, I detected an exceedingly small star close to the planet, and near the third satellite. I at once suspected this to be a new satellite. I at once measured the distance and position-angle of the object with reference to satellite three. I then tried to get measures referred to Jupiter, but found that one of the wires had got broken out and the other loosened. Before anything further could be done the object disappeared in the glare about Jupiter. Though I was positive the object was a new satellite, I had only the one set of measures, which was hardly proof enough for announcement. I replaced the wires the next morning. The next night with the great telescope being Prof. Schaeberle's, he very kindly gave the instrument up to me, and I had the pleasure of verifying the discovery and secured a good set of measures at elongation. In these observations, and those of the succeeding night, only distances from the following limb of Jupiter could be measured. These were observed with the wires set perpendicular to the belts. The planet was thrown outside the field the satellite bisected, and then the limb brought in and bisected also. This method would not permit any measures from the poles of the planet for latitude. On the 12th I inserted a strip of mica, carefully smoked, in front of the field-lens, for occulting the planet. This served admirably, permitting the satellite and planet to be both seen at once, and measures from the polar limbs could be made with great ease. The observations of the satellite from the 12th were all thus made.

"To avoid any personal equation I have on each night measured the diameters of the planet, for use in reducing the observations to the centre of Jupiter. Since the 12th, these have been measured through the smoked mica, so as to avoid introducing any error from the reduced brightness of the planet. The diameters were measured by the method of double distances. Just what the magnitude of the satellite is, it is at present quite impossible to tell. Taking into consideration its position, however, in the glare of Jupiter, it would, perhaps, not be fainter than the thirteenth magnitude. It will only be possible to settle this question with any certainty by waiting until some small star of the same magnitude is seen close to Jupiter, and then after determining its magnitude when away from the planet. In general the satellite has been faint—much more difficult than the satellites of Mars. On the 13th inst, however, when the air was very clear, it was quite easy.

"It is scarcely probable that this satellite will be seen

with anything less than twenty-six inches, and only with that under first class conditions. I give here the observations that I have so far obtained, and defer any suggestions as to a name until a later paper. It certainly should not disturb the present harmony existing in the Roman numerals already applied to the satellites.

"It is so wholly different from any of the other moons in physical aspect, that it ought, in a sense, to be considered independent of them, and simply be called, say, the fifth satellite, with a suitable mythological name.

"It will be seen that on three of the dates of observation the east elongation is well covered in the measures."

Plotting the observations at elongation, the following values of the distance were obtained —

		From Jupiter's centre
		Miles
September 10 (apparent)	61" 04 log R =	7 08267 112250
" 12 "	61" 55 "	7 08452 112750
" 14 "	61" 60 "	7 08324 112400

From these the following periods result, using the well-known formula —

$$P = p \sqrt{\frac{M}{M'}}$$

September 10 period	h	m
" 12 "	11	47.6
" 14 "	11	52.3
Mean	11	49.63

The observations, all made in standard Pacific time (eight hours slow of Greenwich) are given at length in the *Journal*.

The latitude measures show that the satellite's orbit lies in the plane of Jupiter's equator, and Mr Barnard holds that it is consequently a very old member of Jupiter's family, "since it would doubtless take ages for the orbit to be so adjusted."

W L

## NOTES

THE ordinary general meeting of the Institution of Mechanical Engineers will be held on Wednesday evening, October 26, and Thursday evening, October 27, at 25, Great George Street, Westminster. The chair will be taken at half-past seven p.m. on each evening by the President, Dr William Anderson, F.R.S. The ballot lists for the election of new members, associates, and graduates having been previously opened by the Council, the names of those elected will be announced to the meeting. The nomination of officers for election at the next annual general meeting will take place. The following papers will be read and discussed, as far as time permits:—Second Report of the Research Committee on the value of the steam-jacket, by Mr Henry Davey, Chairman (Wednesday), and experiments on the arrangement of the surface of a screw propeller, by Mr William George Walker, of Bristol (Thursday).

WE are asked to intimate that the late Prof Adams has left a number of separate copies of certain of his mathematical and astronomical papers, and that Mrs Adams will be happy to distribute them to scientific friends who make application for them by letter addressed to her at 4, Brookside, Cambridge.

THE Harveian oration was delivered on Tuesday afternoon by Dr J H Bridges. He presented an able and most interesting sketch of the scientific influences amid which Harvey's work was done, and the relation of his great discovery to later research.

THE controversy as to vivisection is still going on in the *Times*. For the present, therefore, it may be enough for us to reproduce the letter which was signed by Sir Andrew Clark, Sir James Paget, Dr Samuel Wilks, and Sir George Humphry,

and printed in the *Times* on Saturday last. It is as follows:—  
"Having already expressed our views, personally or by letter, to the Church Congress, we decline to enter into any further public discussion on the question of so called 'vivisection,' for the following reasons, the statement of which we make solely because we think it is due to your readers:—Firstly, after full consideration, we are satisfied that the scientific aspect of this question cannot receive adequate and just treatment in the columns of a newspaper. Secondly, because it is hardly possible for us to name any progress of importance in medicine, surgery, or midwifery which has not been due to, or promoted by, this method of inquiry."

PROF VIRCHOW was invested, on Saturday last, with the insignia of office as Rector of the University of Berlin. He chose "Learning and Research" as the subject of his address. He acknowledged that study had contributed greatly to create a mutual basis of understanding and a common educational foundation for the peoples of Europe, strengthening at the same time the idea of consanguinity. That state of things, however, was, he thought, entirely changed, and he contended that the turning-point in the supremacy of the classical languages had been reached. "A grammatical education is not the means for progressive development demanded by our youth. Mathematics, philosophy, and the natural sciences give young minds so firm an intellectual preparation that they can easily make themselves at home in any department of learning."

PROF BERG has succeeded the late Dr Hurmeister as director of the National Museum in Buenos Ayres.

DR G V LAGERHEIM, at present director of the Botanic Garden at Quito, Ecuador, has been appointed curator of the museum at Tromsø, Norway.

MR W G RIDGEWOOD, B.Sc., of the Royal College of Science, South Kensington, Assistant to the Director of the Natural History Museum, has been appointed Lecturer in Biology to the St Mary's Hospital Medical School.

THE October number of the *New Bulletin* opens with a section giving some interesting information as to Lao tea. Some time ago a singular method of using the leaves of what has since been proved to be the Assam tea plant of commerce (*Camellia thea*) was brought before the Society of Arts by Mr Ernest Mason Satow. Amongst the Laos, a people inhabiting a district of Siam, in the neighbourhood of Chiengmai, the tea leaves are not used for making an infusion as in other countries, but are prepared wholly for the purpose of chewing. The leaves are first steamed and then tied up in bundles and buried in the ground for a period of about fifteen days. Leaves thus prepared, called locally "mieng," are said to keep for two years or more. The habit of chewing "mieng" is almost universal among the Laos, and to men engaged in hard work, such as piling or rowing, it is said to be almost indispensable. The *Bulletin* prints a correspondence in which the result of an inquiry made by Kew in regard to the plant yielding "mieng" and the method of preparation is detailed.

THE other sections in the October number of the *New Bulletin* deal with Chinese silkworm gut, mangrove bark and extract, Burmese black rice; Mauritius tea, potato disease in Poona, British North Borneo, and Allouya tubers. There are also some miscellaneous notes.

WE learn from the *Journal of Botany* that Dr H Trimen, F.R.S., the Director of the Botanic Gardens at Paladeniya Ceylon, has received the sanction of the Government to proceed with the publication of the flora of that island. The work will be published in parts by Messrs Dalau and Co., and will form two vols. octavo, together with a quarto atlas of 100 coloured plates,

drawn by the native Cingalese artists attached to the gardens. The first part is now in the press. The book is more especially designed for use in the colony, and will enter into more local detail than has been hitherto the practice in the Colonial floras published by the Government.

MR G. HOGGEN delivered an excellent address lately before the Canterbury College Science Society, New Zealand, on earthquakes. In the course of his remarks he described the system which, for the last three years, has been in force in New Zealand for the observation of earthquake phenomena and the telegraphing of the results to a central station. This system has been adopted in Victoria, New South Wales, South Australia, and Tasmania, and will probably be shortly adopted in Queensland. The various colonies exchange reports with New Zealand, and it is proposed that the system shall be further extended, so that the colonies may be brought into communication with the islands of the Pacific and America and Japan.

A REUTER telegram despatched from Vienna on October 14 announced that reports had reached that city of the occurrence of violent earthquake shocks in Eastern Europe. The vibrations were strongest in Roumania, being felt at Bucharest, where they lasted 15 seconds, and at Galatz during 30 seconds. At Oltenizza the shock lasted fully 90 seconds, and did considerable damage in the town. A shock was felt at Sofia on October 14, at seven o'clock A.M., and also at Philippopolis, Varna, and Rustchuk. The seismic wave passed from south to north, the vibration lasting several seconds, and being accompanied by subterranean rumbling.

THE depression over the Bay of Biscay referred to in our last issue took a very unusual route, the track being almost circular, moving first in an easterly and north easterly direction towards the north of France, and then recurving by the south west of England back to the Bay of Biscay, when it again travelled to the eastward. The disturbance caused to the weather in this country was very great and the rains were very heavy, with serious floods, especially in Wales and the midland and northern counties. In Yorkshire it rained almost incessantly from Thursday to Saturday, a fall of 1½ inch being measured in one day. The weather was still further disturbed by an area of low pressure lying over the north of Germany between Sunday and Monday, which caused disastrous gales and further heavy rains in the eastern part of the country. The temperature has been very low for the season, the daily maxima scarcely reaching 55° in any part of the kingdom, owing to the persistent northerly and north easterly winds. Towards the close of the period temperature fell several degrees lower, with sharp day frosts in Ireland, under the influence of an anti-cyclone, which spread over the country from the Atlantic, while hail and sleet showers fell in places. The *Weekly Weather Report* of the 15th inst. showed that the temperature of the past week was everywhere below the mean, being as much as 4° in the south-west of England and 5° in the south of Ireland. The rainfall greatly exceeded the average over the north and east of England.

AN anemometer by M. Timchenko of a novel construction is described by Prof. Klossovsky, of the Odessa Observatory, by which both the wind direction and velocity are marked on a cylinder by one symbol. The recording apparatus is moved by clockwork and the indications are made by electrical contacts. The duration of the contact depends upon the velocity of the wind, a light wind producing a contact of longer duration than a strong one. The indications are by means of arrows printed on the paper covering the cylinder, which show the direction of the wind, and the number of arrows marked on a length of paper corresponding to one hour furnishes data for finding the velocity by an empirical scale determined by comparison with a Robinson's anemometer. The apparatus only requires to be adjusted twice a month, or in some instruments only once a month, and

calls for no attention in the meantime. A battery cell is sufficient to produce the contact, for most of the work is done by means of weights.

THE *Annuaire* of the Municipal Observatory of Montsouris for the years 1892-93 contains, in addition to the usual tables showing *inter alia* the extremes of temperature at Paris since 1699 and the monthly rainfall values since 1690, much useful information with reference to the climate and the microscopic examination of the quality of the air. Although it does not fall within the province of the observatory to issue weather forecasts, applications for such information are sometimes received and answered, in the interest of agriculture. The opinion is expressed that by basing the calculations on the general methods adopted by Laplace in his memoir entitled "Probabilité des causes d'après les événements," it is not impossible to give a long forecast which may be at times of much use. Some interesting remarks are also made as to the possibility of foreseeing the character of the summer from the weather experienced in the early spring, based chiefly on the time of the appearance of the north east winds, and the differences in their usual strength and physical qualities, in connection with the transparency of the air. The results of the analysis of the air show that the minimum amount of carbonic acid occurs between May and September, and that the amount at night is greater than during the day.

THE new University of Chicago has decided that its work shall go on all the year through, including the summer months. According to the *New York Nation*, the calendar year is divided into four quarters of twelve weeks each, beginning respectively on the first days of October, January, April, and July, and at the end of each quarter there is to be a recess of one week. Each quarter consists of two terms of six weeks. No student is to be held to an attendance of more than three quarters, or six terms, in each year, so that the normal academic year is no longer than at other colleges. Each student is to begin his academic year whenever he is ready, and to take his quarter's vacation whenever it suits his convenience. He may even take his two terms of vacation in different quarters.

AN investigation of the phenomena exhibited at the negative poles of vacuum tubes appears in vol. xl of the *Sitzungsberichte* of the Prussian Academy. Professor E. Goldstein considers that the term "stratification" as applied to the light at the cathode is a misnomer, since two at least of the strata can be shown to pervade the entire region of luminosity. The light nearest the cathode is yellowish, and about 1 cm thick. Next comes Crookes' "dark space," which in reality shines with a faint blue light. Then follows the third and most highly luminous layer, whose colour changes from a blue to a violet as the exhaustion is carried further. The first layer was shown to be a separate phenomenon on a previous occasion. The so-called second layer shows the peculiarity of rectilinear propagation. It is emitted from the electrode normally to its surface, or very slightly divergent, whereas that of the third layer spreads throughout the bulb and even passes round corners. The second layer is best shown by concave poles, which concentrate the light at the centre of curvature. If observed through a blue glass, which cuts off the third layer, it is seen to diverge from the focus and impinge upon the wall of the bulb. The phosphorescence observed in the glass where it is struck by the "radiant matter" is due to this part of the light only, and not to the third layer. It is this also which produces the well-known phenomena of shadows. A glass rod laid in its path casts a shadow through the blue space, which is, however, relieved by the purple luminosity of the third layer. The former is also the only light deflected by a second cathode. It is to be concluded that the light at the negative pole of a vacuum tube consists of three different species, each pervading the others, but having distinct and characteristic properties of its own.

IN the current number of the "Annals of Scottish Natural History," Mr E P Knubley discusses the question whether legislative protection is required for wild birds' eggs. He suggests that the most practicable plan might be for Parliament to grant powers to the County Councils from time to time, and as necessity arose, to place certain portions of a district, such as mountains, commons, waste places, lakes and meres, or portions of cliffs or foreshores, under an Act for specified months in the year—say, from April 1 to June 30. What, however, is most urgently wanted, as Mr Knubley says, is that landlords and occupiers shall, as far as possible, protect birds breeding on their property or "occupation."

MR ERNEST ANDERSON recently read before the Field Naturalists' Club of Victoria an interesting paper on some Victorian Lepidoptera. He said that a great charm accompanied the rearing out of the Victorian species, because the results were very frequently of a most unlooked for character. The Victorian forms followed the same rule as many plants and animals in having characteristics and habits purely Australian, and not only so, but they helped to bridge over the sharply defined divisions known in Europe, and merged the various groups so imperceptibly into each other that it was hard to say where one ended and another began. Speaking of the processional caterpillars (*Zeara melanosticta*), Mr Anderson described how a female laid some ova in a small box and covered them very thickly with yellow down. Very shortly afterwards a thread like structure was visible, which close examination revealed to be composed of newly-hatched caterpillars in Indian file, each having its head close up to the tail of its forerunner, and the whole line moving simultaneously with mathematical precision.

THE use of gas engines does not seem to be nearly so common in the United States as in Great Britain. According to the *Railroad and Engineering Journal*, they are generally regarded in America as of service for light work only, and it is with some surprise that our contemporary has noted the advertisement of an English firm, which keeps all sizes up to forty horse power in stock, and offers to furnish single engines of any size up to two-hundred and fifty-horse power. This much exceeds the capacity of any gas engine built until very recently.

THE U.S. Department of Agriculture has published a valuable account, by Harvey W. Wiley, of experiments with sugar-beets in 1891. The experiments were divided into three classes, (1) culture of the sugar beet conducted by farmers in different parts of the country, (2) culture of the sugar-beet conducted by the agricultural experiment station of Wisconsin and numerous farmers in Wisconsin, under the direction of the agricultural experiment station of that State, by authority of the Secretary of Agriculture, (3) experiments conducted at the beet sugar experiment station of the Department at Schuyler, Nebraska.

WE learn from the *American Naturalist* for October that the vertebrate fossils collected by Prof. Marsh, to which we lately referred, are not likely, after all, to be soon exhibited in the National Museum at Washington. Our contemporary says: "One side of a small room is the only space at present occupied by the material in question, and it is safe to say that no other space has been yet provided. As the National Museum committed the error at its establishment of attempting an exhibit of modern human industries, as we pointed out at the time, the space for scientific exhibits is necessarily greatly curtailed. The necessities of this department require the erection of a new building, and until that is done it is safe to say that the vertebrate collections of the U.S. Geological Survey will not be exhibited."

SLEEP is one of the least understood of physiological phenomena. A new theory of it (we learn from the *Revue Scientifique*) has been offered by Herr Rosenbaum. He supposes the essential fact in the fatigue of the nervous system leading to sleep to be a hydration of the nerve-cells, an increase of their water-content. The greater the hydration, the less the irritability. This hydration arises through chemical change of the nervous substance during activity. A small part of the water escapes by day through the lungs, but the greater part is eliminated during sleep. Its passage into the blood takes place by virtue of the laws of diffusion, and depends on the quantity and density of the blood, its amount of fixed principles, its speed of flow, &c. Elimination of the expired air takes place according to the laws of diffusion of gases. The assimilable substances of the body take the place of the water eliminated in sleep. The repair of the physical and mental forces through sleep is due to this elimination and replacement. Intelligence is in inverse ratio of the proportion of water in the brain, and may be measured by this proportion, at least in the child. It may be doubted whether this theory explains the sleep of hibernating animals, or that caused by opium and anæsthetics.

D. J. MADISON TAYLOR has been elaborately investigating the various problems relating to physical exercise in health and as a remedy, and some of the results are set forth in the *Journal of the Franklin Institute* for September and October. One conclusion is, he says, uniformly prominent in the instances of damage from boat and other racing. Always the training has been "either insufficient or bad, or both."

IN one of the papers contributed to the third number of the Trinidad Field Club's Journal, Mr J. Edward Tanner describes some interesting observations of the habits of the Parasol or Leaf Cutting Ants. Two nests of these ants were on his table at the time when his paper was being prepared. He begins by noting that all in Trinidad who are interested in such subjects know the hurried manner in which a parasol ant returns to her nest (all leaf cutting workers are females), bearing erect in her mandibles the portion of leaf she has herself just cut off, and apparently running home with it in triumph. These foragers, for they are the ones who supply the household, carry their portion of a leaf well into the nest, drop it, and return for another piece, nor do they cease doing so till the supply is more than those in the nest require. Mr Tanner could not induce the ants in one of his nests to carry any leaf whatsoever into the nest, till one day he coaxed a small worker to do so. As she entered she was caressed by those in the nest, who stroked and patted her with their antennæ. The small piece of leaf she had brought was at once taken by one of the larger workers, to go through its various processes, while she returned for more, and she continued to bring in pieces till late in the evening. Strange to say, none of the others followed her example. Even four weeks later only two or three carried in any portions of leaf. Mr Tanner suggests that this may have been due to the fact that the queen was accidentally killed while the nest was being taken. The other nest had a queen, and with it there was no trouble, for the ants kept themselves well supplied from whatever was offered to them on their feeding ground, whether rose leaves, plumbago, or quinquinalis. "Each forager," says Mr. Tanner, "drops her portion of leaf in the nest, which is taken up as required by the small workers, and carried to a clear space in the nest to be cleaned. This is done with their mandibles, and if considered too large it is cut into smaller pieces. It is then taken in hand by the larger workers, who lick it with their tongues. Then comes the most important part, which almost always is done by the larger workers, who manipulate it between their mandibles, mostly standing on three legs. The portion of leaf is turned round and round between the mandibles, the ant using her palpi, tongue, her three legs, and her antennæ while doing so. It

now becomes a small, almost black ball, varying in size from a mustard seed to the finest dust shot, according to the size of the piece of leaf that had been manipulated. The size of the piece of leaf is from an  $\frac{1}{8}$  by  $\frac{1}{8}$  of an inch, by  $\frac{1}{4}$  by  $\frac{1}{4}$  of an inch. I do not wish it to be understood that only one class of workers manipulate the leaf, for all seem to take to it very kindly on emergency. Even the smallest workers will bring their tiny ball to where the fungus bed is being prepared. These balls, really pulp, are built on to an edge of the fungus bed by the larger workers, and are slightly smoothed down as the work proceeds. The new surface is then planted by the smaller workers, by slips of the fungus brought from the older parts of the nest. Each plant is planted separately and they know exactly how far apart the plants should be. It sometimes looks as if the plants had been put in too scantily in places, yet in about forty hours, if the humidity has been properly regulated, it is all evenly covered with a mantle, as if of very fine snow. It is this fungus they eat, and with small portions of it the workers feed the larvæ.

MR. O. P. HAY records in the latest volume of the Proceedings of the U. S. National Museum a curious habit of horned toads. Some years ago two boys from Texas, whose family had moved into his neighbourhood, showed him a few lizards belonging to the genus *Phrynosoma*, and popularly called horned toads. The boys declared that these little animals, when teased, would sometimes squirt blood out of their eyes. Mr. Hay did not think much about the matter at the time, but was lately vividly reminded of it in the department of reptiles in the National Museum. Near his desk there was a specimen of *Phrynosoma coronatum*, which had been sent from California by a member of Dr. Merriam's exploring party. About August 1 it was shedding its outer skin, and the process appeared to be a difficult one, since the skin was dried and adhered closely. One day it occurred to Mr. Hay that it might facilitate matters if he gave the animal a wetting, so, taking it up, he carried it to a wash-basin of water near by and suddenly tossed the lizard into the water. "The first surprise," says Mr. Hay, "was probably experienced by the *Phrynosoma*, but the next surprise was my own, for on one side of the basin there suddenly appeared a number of spots of red fluid, which resembled blood." He immediately recalled what the boys had told him of the ability of horned toads to squirt blood, and he concluded that this was a good time to settle the question whether this fluid was blood or not. A microscope was soon procured and an examination was made, which immediately showed that the matter ejected was really blood. A day or two afterwards Mr. Hay was holding the lizard between his thumb and middle finger, and stroking its horns with his forefinger. All at once a quantity of blood was thrown out against his fingers, and a portion of it ran down on the animal's nose and this blood came directly out of the right eye. Mr. Hay has since found that the phenomenon has been noticed by other observers, and, while he was preparing his paper, his attention was called to the fact that more than twenty years ago Mr. A. R. Wallace read before the Zoological Society of London letters from a correspondent in California, who described this creature as squirting from one of its eyes "a jet of bright red liquid very much like blood."

MESSRS. PERCIVAL AND CO. announce the following works:—"Geometrical Drawing," by A. J. Pressland, "Lessons on Air," by A. E. Hawkins, "The School Euclid," an edition of Euclid, Books I-VI, with Notes and Exercises, by Daniel Brent; and a series of elementary text-books entitled "The Beginner's Text-books of Science," of which Mr. G. Stallard is the general editor.

MESSRS. GEORGE BELL AND SONS have published a second edition of Mr. A. J. Jukes-Browne's "Student's Handbook of Physical Geology." The author explains that in preparing this

edition he has spared no pains to make it a trustworthy handbook for those branches of the science to which it relates.

MESSRS. WHITTAKER AND CO. have issued for the benefit of amateur coil-makers a practical manual on "Induction Coils," by G. E. Honney. The author's object has been to place in the hands of his readers "a cheap and handy volume giving a general insight into the construction of ordinary spark coils, medical coils, and batteries for working them." There are more than a hundred illustrations.

MESSRS. LONGMANS, GREEN, AND CO. have issued a new edition, revised and largely re-written, of the well-known "Outlines of Psychology," by Prof. James Sully.

MESSRS. CHAPMAN AND HALL will shortly publish a work by Rev. H. N. Hutchinson, entitled "Extinct Monsters." It will be illustrated by Mr. J. Smit, who has made twenty-four restorations of antediluvian animals. The book is not intended for geologists only, but for all who are interested in the study of animal life. Dr. Henry Woodward, F.R.S., keeper of geology, Natural History Museum, contributes a preface.

THE new number of *Records of the Australian Museum* (Vol. III, No. 2) opens with a paper, by Mr. J. Douglas Ogilby, on some undescribed reptiles and fishes from Australia. To the same number Mr. C. Hedley contributes a paper on the structure and affinities of *Panda Atomata*, Gray. Mr. A. North has a note on *Manucodia comris*, Sclater.

THE University College of North Wales has published its calendar for the year 1892-93.

GLYCOL aldehyde,  $\text{CH}_2\text{OH}\cdot\text{CHO}$ , the hitherto almost unknown first aldehyde derived from glycol, forms the subject of a communication to the current number of the *Berichte* by Prof. Emil Fischer and Dr. Landsteiner. This substance acquires additional interest when the ordinary sugars are defined as aldehyde- or ketone-alcohols, for it then becomes the first member of the series. Prof. Fischer now shows how glycol aldehyde may readily be obtained, discusses its properties, and points out that by its polymerisation a new sugar is obtained, tetrose, the first synthetical sugar containing four atoms of carbon. The only evidence hitherto published of the existence of glycol aldehyde is that afforded by the work of Abeljan and Pinner. The former chemist considered that he had obtained it by heating di-chlor ether with water, and by the action of sulphuric acid upon mono-chlor-hydroxy-ether. But upon repeating the work of Abeljan, Prof. Fischer finds that the substance considered, upon very slight evidence, to be glycol aldehyde is another compound altogether. Pinner afterwards attempted to obtain it by decomposition of a substance discovered by him, glycol acetal, with acids, but Prof. Fischer finds that this reaction only occurs under conditions such that the glycol aldehyde is itself also decomposed. In view of the formation of glycyl aldehyde by the action of baryta upon acrolein dibromide, a reaction now of historical importance as being the one which led Prof. Fischer to the first synthesis of grape sugar, it was thought probable that glycol aldehyde might be similarly obtained by the action of baryta upon the mono-bromine derivative of aldehyde,  $\text{CH}_2\text{Br}\cdot\text{CHO}$ . Mono-brom-aldehyde, however, had never been hitherto obtained, so Prof. Fischer and Dr. Landsteiner first sought a method for its preparation. They eventually obtained it, as a viscid colourless liquid of powerful tear-exciting odour, by heating mono-brom-acetal,  $\text{CH}_2\text{Br}\cdot\text{CH}(\text{OC}_2\text{H}_5)_2$ , with anhydrous oxalic acid. When the mono-brom-aldehyde thus

obtained was mixed with water containing barium hydrate partly in solution and partly in suspension, and the whole maintained for half an hour at 0°, the odour of the brom aldehyde disappeared almost completely. Upon removal of the baryta by sulphuric acid and the hydrobromic and sulphuric acids by lead carbonate, the filtered liquid was found to contain glycol aldehyde, which could be concentrated by evaporation over oil of vitriol *in vacuo*. The solution of glycol aldehyde reduces Fehling's solution with great energy at the ordinary temperature. When warmed with a solution of phenylhydrazine in acetic acid crystals of an osazone are deposited, just as happens in the case of other members of the series of sugars. Glycol aldehyde is readily oxidized by bromine water to glycollic acid,  $\text{CH}_2\text{OH}\cdot\text{COOH}$ . When treated with a dilute solution of sodium hydrate polymerization occurs, a sugar of the composition  $\text{C}_4\text{H}_8\text{O}_4$ , the first synthetical tetrose, being formed, which is readily isolated in the form of its osazone (phenyl hydrazine compound). This osazone appears to be identical with one obtained by Prof. Fischer from one of the oxidation products of natural erythrite. The preparation of glycol aldehyde completes the synthesis of the whole of the members of the series of sugars, from the first member up to the sugars containing nine atoms of carbon, with the exception of pentose. This latter sugar Prof. Fischer hopes shortly to obtain from the tetrose above described.

THE additions to the Zoological Society's Gardens during the past week include a Grivet Monkey (*Cercopithecus griseo virens* ♀) from Zanzibar, a Bengal Fox (*Canis bengalensis*) from Pondicherry, presented by the Rev J. W. Scarlett, a — Monkey (*Cercopithecus sp. inc.*) from the Zambesi, presented by Mr. Joseph A. Moloney, a Bonnet Monkey (*Macacus sinicus*) from India, a White Stork (*Ciconia alba*), European, presented by the Rev. Sidney Vatcher, a Mona Monkey (*Cercopithecus mona*) from West Africa, presented by Miss Syngé, a hairy Armadillo (*Dasypus villosus*) from South America, presented by Mr. J. H. Hamilton Benn, a Common Badger (*Meles taxus*), British, presented by Mr. W. Butler, a — Galago (*Galago sp. inc.*) from East Africa, presented by Mr. Thomas E. C. Remington, an — Ichneumon (—), a Purple crested Touracou (*Corythaix porphyreolophus*), two Black Gallinules (*Limnocorax niger*), a Tambourine Pigeon (*Tympanistris bicolor*), an Emerald Dove (*Chalcophaps ufer*), four Half collared Doves (*Turtur semitorquatus*), a — Fruit Pigeon (*Liberon sp. inc.*), four — Tree Frogs (*Hylambates maculatus*), seven Smooth clawed Frogs (*Xenopus levis*) from East Africa, presented by General Mathews, three Mitted Guinea Fowls (*Nunida mitrata*), a — Snake (*Philothamnus semivariegatus*) from East Africa, presented by Mr. W. Hall Buxton MacDonald, M.D., a — Pratincole (*Glareola sp. inc.*), a Half-collared Dove (*Turtur semitorquatus*), a Nilotic Crocodile (*Crocodilus niloticus*) from East Africa, presented by Mr. R. MacAllister, two — Francolins (*Francolinus* —), a — Coucal (*Centropus* —), five Half collared Doves (*Turtur semitorquatus*) from East Africa, a Black tailed Hawfinch *Coccothraustes melanurus*) from Japan, presented by Mr. F. Pordage, a Flap-necked Chameleon (*Chamaeleo dilepis*), two Square marked Toads (*Bufo regularis*) from East Africa, presented by Mr. E. Millar, a Galeated Pentonyx (*Pelomedusa galeata*), two — Skinks (*Gerrhosaurus major*), five — Geckos (*Hemidactylus mabouia*), three — Lizards (*Mabouia striata*) from East Africa, presented by Mr. Frank Finn, F.Z.S., a Common Quail (*Coturnix communis*), captured at sea, presented by Mr. A. Torrie, a Honey Buzzard (*Buteo apivorus*) from France, presented by M. S. A. Pichot, C.M.Z.S., a Burrowing Owl (*Sporiolyto cucularia*) from South America, presented by Mr. R. B. Shipway, two Common Boas (*Boa constrictor*) from Trinidad, presented by Messrs. Mole and Ulrich, a Black-headed Lemur (*Leimur brunneus*) from Mada-

gascar, a Yellow tailed Rat Snake (*Splotes corais*) from Trinidad, deposited, an African Wild Ass (*Equus hemionus*), born in the Gardens.

### OUR ASTRONOMICAL COLUMN

A NEW COMET — A telegram from Kiel announces the discovery of a new comet by Prof. Barnard on October 12 last, at 17h 12m mean Lick time. The position, as therein stated, was R.A. 293° 29', and Declination + 12° 33'. As this new comet is termed "very dim," as seen with the large Lick refractor, it is needless to say that few instruments can at present observe it.

OUR SUN'S HISTORY — The question of "How our Sun commenced to grow hot," is the subject of an article by Lord Kelvin in the October number of *L'Astronomie*. In these few pages he deals with various questions, among which may be mentioned: What is the temperature of the Sun? Is it increasing or diminishing? What was the state of the matter constituting our Sun before it was united into a single mass and began to grow hot? The answer to the last question leads him into the method of construction of our solar system. In considering the question of the encounter between two bodies as the origin, he finds that the probability of such an encounter between two neighbouring stars belonging to a large number of bodies, attracting one another mutually, and scattered in space, is much greater if they are at rest than if they are moving, even if their velocities are greater than those acquired in falling from rest. As an explanation of this Lord Kelvin takes the case of two solid and cold bodies of diameters equal to half that of the sun, and of mean densities equal to that of the earth, and supposes them at rest, the mean distance between each other being that of the earth from the sun. The collision caused by mutual attraction will transform the bodies into a fluid, incandescent mass, and he describes how this mass will arrange itself round this surface of collision. The next case he takes is similar to the one above, only the bodies have originally considerable velocities. Further on, as a special instance, he assumes the presence of 29 millions of solid cold globes, each having a mass equal to that of our moon, and the total masses of which are equivalent to that of our sun. These bodies, absolutely at rest, are supposed to be disseminated uniformly on the surface of a sphere (radius = terrestrial orbit), and allowed to fall towards the centre of the sphere by attraction. The result, to state briefly, is a mass of highly heated vapour, which afterwards expands and contracts consecutively, forming a gaseous nebula, measuring forty times the radius of the terrestrial orbit. By supposing that, instead of absolute rest at the commencement, these moons have a certain movement, the total sum of which represents a moment of rotation round a certain axis, equal to the moment of rotation of the solar system, this nebula would be a more or less facsimile of our solar system in its earlier stage, as figured out by La Place for his nebular theory. Thus this theory, "founded by La Place on the history of the sidereal universe such as Herschel observed, and completed in its details by his profound dynamical judgment and imaginative genius, appears to lay a truth demonstrated by thermodynamics." For the theory of the sun, Lord Kelvin says in conclusion that the antecedents immediately before incandescence cannot be definitely stated, since the latter may have been caused by large and few bodies, or by agglomerations of such bodies as meteorites.

SILVERING GLASS MIRRORS — Mr. Common, in the *Observatory* for October, gives a brief account of various processes and methods for producing good reflecting surfaces. In the short historical sketch we find that the modern process is due to an observation of Baron Liebig, who, in 1835, found that on heating aldehyde with an ammoniacal solution of silver in a glass vessel a brilliant deposit of metallic silver was deposited on the surface of the glass. In all the methods used up till quite recently the surface to be silvered had to be suspended over the bath, owing to the formation of mud which settles down and prevents the proper deposition of silver, thus really large surfaces could not be dealt with. This was the case with Mr. Common's 3 foot, a pneumatic arrangement being made to hold the mirror by the back. In dealing with the 5 foot, this method could not be so easily applied, and experiments were made to find some means by which this "mud" could be entirely eliminated. This was successfully

done by omitting the potash from the bath. One curious fact of observation is that the mirrors experimented on never seemed to take the first application of the silvering solution, but on being re-cleaned with nitric acid the second was always successful. Why this should be so does not seem to be easily explained, for Mr. Common only commits himself to the statement that "the nature of the liquid other than distilled water last in contact with the surface of the mirror seems to be the determining thing."

*Himmel und Erde*—In this magazine for October there is a most interesting set of articles, of which we mention the following—"Meteorology as the Physics of the Atmosphere," by Herr Wilhelm von Bezold. This comprises a general summary of the proceedings of the German Meteorological Society, which met in Braunschweig on June 7 last—"Astronomy of the Invisible," by Herr Dr. Scheiner. This is the first of a series of articles, and deals, as far as it goes, with the discovery of Neptune by Adams and Le Verrier; it contains also a translation of the letter which Le Verrier wrote to Dr. Galle, who was then an assistant at the Berlin Observatory, telling him the results he had obtained, and asking him to make a search for the unknown planet. As a matter of interest we will give the elements of Neptune as obtained by Le Verrier and Adams, together with the true ones afterwards determined, for the results of such a piece of work will always be looked upon with interest.

	Le Verrier	Adams	True elements
Half major axis	36.15	37.25	30.05
Eccentricity	0.1076	0.1206	0.0090
Longitude of Perihelion	285°	299°	46°
Mass (Sun = 1)	0.0001	0.00015	0.00005
Inclination	0"	0"	1° 8'

In the notes two excellent illustrations of parts of the moon are inserted, one being a reproduction of a photograph taken at the Lick Observatory on August 31, 1890, and the other displaying the region to the north of Hyginus, showing these curious river-like appearances as first remarked by Prof. Weinek of Prague. Other notes deal with the astronomical reasons of the Ice Age, observations of Mars during the period 1883-88, polariscope observation of the surface of Venus, &c.

### GEOGRAPHICAL NOTES

MOUNT ORIZABA, or Citlaltépetl, in Mexico, has been measured trigonometrically by Mr. J. T. Scovell, with the result that its height is fixed as 18,314 feet. Popocatepetl is about 700 feet lower, and unless Mount St. Elias is found to considerably exceed Russell's estimate of 18,100 feet, Orizaba must be considered the highest summit in North America.

The pumping of brine from the North German salt mines and the consequent subsidence of the land, is the cause of a somewhat interesting change in the small lakes near Mansfeld. The Salzigen See, as observed by Dr. Ule, of Halle, had a maximum depth of thirty metres on June 18, and of no less than forty two metres on June 28, the subsidence of the bottom having taken place at the average rate of more than one metre a day.

FOLLOWING the death of Dr. Theodor Menke (see p. 302) we have to notice the loss of his fellow-worker, Dr. Karl Spruner von Merz, at the age of eighty-nine. He died on August 24, 1892. After a military career of some distinction, he retired from the army in 1886. His attention was early attracted to historical geography, and his famous "Historical Atlas" (1837-1852) has made his memory imperishable. It was in preparing the third edition of this atlas that he was first associated with Menke.

THE camels which were introduced into German South-West Africa last year, have, according to the *Deutsches Kolonialblatt*, proved a great success. They are employed in keeping up communication between Walvisch Bay and Windhoek, and for journeys into the interior. Their power of travelling for a week at a time without food or water has frequently been put to the test on the borders of the Kalahari desert. The climate does not seem to affect them unfavourably, and they have proved exempt from the many fatal diseases which attack horses and even oxen in Namaqualand.

A LECTURE on "Regions and Races" was delivered on Monday evening in the Regent's Square Hall by Dr. H. R. Mill.

NO. 1199, VOL. 46]

The object of the lecture was to demonstrate the continuity of geography with the physical sciences which account for the growth of the surface features of the globe, and with the natural sciences which explain the forms of plant and animal life on its surface. The interactions between man and his environment were discussed as the true basis of the higher geography.

M. J. THOULET has this summer been engaged in an oceanographical study of the Basin of Arcachon, and publishes in the last number of the *Comptes Rendus* an interesting epitome of his preliminary results. This lagoon forms a valuable oyster preserve, and the researches into the action of the tides on the enclosed water has practical as well as scientific bearings. The investigation will be continued, so as to include the other lagoons along the coast enclosed by sand dunes, and more or less cut off from the sea.

### THE COMPARATIVE PHYSIOLOGY OF RESPIRATION<sup>1</sup>

AMONG the very first of the physiological acts observed were those of respiration. The regular movements of breathing, from the first feeble efforts of the new-born babe until the sigh in the last breath of the dying—after which is silence, cold, and dissolution—have commanded the attention and claimed the interest of every one, the thoughtful and the thoughtless alike. And one comes to feel that in some mysterious way "the breath is the life." But in what way does breathing subserve life or render it possible? Aristotle and the naturalists of the olden time supposed that it was to cool the blood that the air was taken into the lungs, and, as they supposed, also into the arteries. With the limited knowledge of anatomy in those early days, and the fact that after death the arteries are wholly or almost wholly devoid of blood, while the veins are filled with it, what could be more natural than to suppose that the arteries were vessels for the cooling air? If one supposes that he has entirely outgrown this view of Aristotle, let him think for a moment how he would express the fact that an individual is descended from the Puritans, for example. In expressing it even the physiologist could hardly bring himself to say other than "he has the blood of the Puritans in his veins." Would he say "he has the blood of the Puritans in his arteries?"

As observation increased the cold-blooded animals were more carefully studied and found to possess also a respiration, they certainly do not need it to cool the blood. Then there are the insects and the other myriads of living forms that teem in the oceans, lakes, rivers, and even in the wayside pools. Do these, too, have a breath? And the plants on the land and in the water, is the air vital to them? Aristotle and the older naturalists could not answer these questions. To them, on the respiratory side at least, all life was not in any sense the same. It was not till chemistry and physics were considerably developed, not until the air-pump, the balance, and the burette were perfected that it was possible to give more than a tentative answer. It was not, until the microscope could increase the range of the eye into the fields of the infinitely little, possible to form even an approximately correct conception. The first glimmerings of the real significance of respiration for all living things was in the observation that the air which would not support a flame, although it might be breathed, could not support life. That is, there must be something in the transparent air that feeds the flame and becomes the breath of life, the real *subulum vite*, the merely mechanical action of the air not being sufficient.

Since the experiments on insects and other animals by Boyle (1670) with the air pump, by Bernoulli, on subjecting fishes to water out of which all the air had been boiled, and those of Mayow (1674), it became more and more evident that respiration was not confined to the higher forms, but was a universal fact in the organic world. Then came the most fruitful discoveries of all, made by the immortal Priestley (1775-6), viz., that the air is not an element, but composed of two constituents—nitrogen, which is inert in respiration, and oxygen, which is the real vital substance of the air, the substance which supports the flame of the burning candle and the life of the animal as well.

What would seem more simple at this stage of knowledge

<sup>1</sup> Address delivered, in August, 1892, at the meeting of the American Association for the Advancement of Science, by Prof. Simon Henry Gage, of Cornell University, Ithaca, N. Y., Vice President of the Biological Section.

than that the parallel between the burning candle and the living organism should be thought to represent truly the real conditions? That as the candle consumes the oxygen, burns, and gives out carbon dioxide, so the living thing breathes in oxygen, and gives out in place of that consumed carbon dioxide. And as in each case heat is produced, what would be more natural than to look upon respiration as a simple combustion? This was the generalization of Lavoisier (1780-89). As he saw it, the oxygen entered the lungs, reached the blood, and burned the carbonaceous waste there found, and was immediately given out in connection with the carbon with which it had united, and as the gas given off in a burning candle makes clear lime water turbid, so the breath produces a like turbidity.

But here, as in many of the processes of nature, the end products or acts were alone apparent, and while the fundamental idea is probably true that respiration is, in its essential process, a kind of combustion or oxidation, yet the seat of this action is not the lungs or blood. If the myriads of microscopic forms are considered, these have no lungs, no blood, and many of them even no organs; they are, as has been well said, organless organisms, and yet every investigation since the time of Vinci and Von Helmont, Boyle and Mayow, has rendered it more and more certain that every living thing must in some way be supplied with the vital air or oxygen, and that this is in some way deteriorated by use, and the nearer investigation approaches to the real life stuff or protoplasm, it alone is found to be the true breather, the true respirer, as was shown long ago by Spallanzani (1803-7). If one of the higher animals, as a frog, is decapitated and some of its muscle or other tissue exposed in a moist place, it will continue to take up oxygen and give out carbon dioxide, thus apparently showing that the tissues of the highly organized frog, may, under favourable conditions, absorb oxygen directly from the surrounding medium, and return to it directly the waste carbon dioxide. This shows conclusively that it is the living substance that breathes, and the elaborate machinery of lungs, heart, and blood-vessels, are only to make sure that the living matter, far removed from the external air, shall not be suffocated. Still more strange, it has been found that if some of the living tissue is placed in an atmosphere of hydrogen or nitrogen entirely devoid of oxygen, it will perform its vital functions for a while, and although no oxygen can be obtained, it will give off carbon dioxide as in the ordinary air. If it is asked, "how can these things be?" the answer is apparently plain and direct. Not as the oxygen unites directly with the carbon in the burning candle does it act in the living substance. The oxidations are not direct in living matter, as in the candle, but the living matter first takes the oxygen and makes it an integral part of itself, as it does the carbon and nitrogen and other elements, and, finally, when energy is to be liberated, the oxidation occurs, and the carbon dioxide appears as a waste product.

The oxygen that is breathed to day, like the carbon or the nitrogen that is eaten, may be stored away and represent only so much potential energy to be used at some future time in mental or physical action.

So far only living animal substance has been discussed. If plants are considered, what can be said of their relations to the air? The answer was given in part by Priestley (1771), who found that air which had been vitiated by animal respiration became pure and respirable again by the action of green plants. He thus discovered the harmonizing and mutual action of animals and plants upon the atmosphere, and there is no more beautiful harmony in nature. Animals use the oxygen of the air and give to it carbon dioxide, which soon renders it unfit for respiration, but the green plants take the carbon dioxide, retain the carbon as food and return the oxygen to the air as a waste product. This is as thoroughly established as any fact in plant physiology, and yet, in his experiments, Priestley had some of what he called "bad experiments", for instead of the plants giving out oxygen and thus purifying the air, they sometimes gave off carbon dioxide, and thus rendered it more impure, after the manner of an animal. What investigator cannot sympathize with Priestley when he calls these "bad experiments"; they appeared so rudely to put discord into his discovered harmony of Nature. But Nature is infinitely greater than man dreams. The "bad experiments" were among the most fruitful in the history of scientific discovery. Ingenhousz (1787) followed them up, carefully observing all the conditions, and found that it was only in daylight that green plants gave out oxygen, in darkness or insufficient light they conducted themselves like animals, taking up

oxygen and giving out carbon dioxide. Finally it was proved by Sussure (1804) and others, that for green plants, and those without green, like the mushroom, oxygen is as necessary for life as for animals. It thus became evident that this use of oxygen and excretion of carbon dioxide was a property of living matter, and that the very energy that set free the oxygen of the carbon dioxide was derived from oxidations in the green plant comparable with those giving rise to energy in animals. Further that the purification of the air by green plants in light is a separate function—a chlorophyll function—as it has been happily termed by Bernard—and resembles somewhat digestion in animals, the oxygen being discarded as a waste product. Indeed so powerful is the effort made to obtain oxygen for the life processes by some of the lowest plants—the so called organized ferments—that some of the most useful and some of the most deleterious products are due to their respiratory activity. In alcoholic fermentation, as clearly pointed out by Pasteur and Bernard, the living ferment is removed from all sources of free oxygen, and in the effort for re-purification the molecules of the sugar are decomposed or rearranged and a certain amount of oxygen set free.

It has been found that the motile power of some bacteria like *Bacterium termo* depends on the presence of free oxygen in the liquid containing them. When this is absent, they become quiescent. This fact has been utilized by Engelmann and others in the study of the evolution of oxygen by green and other coloured water plants. The bacteria serving as the most delicate imaginable oxygen test, so that when the minutest green plant is illuminated by sufficient daylight, the previously quiescent bacteria move with great vigour and surround it in swarms. Out of the range of the plant, the bacteria are still, or move very slowly, as if to conserve the minute energy developing substance they have in store until it can be used to the best advantage.

May we not now approach the problem directly, and answer for the whole organic living world the question, "What is respiration?" by saying it is the taking up of oxygen and the giving out of carbon dioxide by living matter? This is the universal and essential fact with all living things, whether they are animals or plants, whether they live in the water or on land. But the ways by which this fundamental life process is made possible, the mechanisms employed to bring the oxygen in contact with the living matter, and to remove the carbon dioxide from it, are almost as varied as the groups of animals, each group seeming to have worked out the problem in accordance with its special needs. It is possible, however, in tracing out these complex and varied methods and mechanisms, to discover two great methods—the Direct and the Indirect.

In the first, there is the direct assumption of oxygen from the surrounding medium, and the excretion of carbon dioxide directly into it. The best examples of this are presented by unicellular forms like the amoeba, where the living substance is small in amount, and everywhere laved by the respiratory medium. But as higher and higher forms are destined to appear, evidently the minute, organless amoeba could not in itself realize the great aim toward which Nature was moving. There must be an aggregation of amoebae, some of them serving for one purpose and some for another. Like human society, as civilization advances, each individual does fewer things, becomes in some ways less independent, but in a narrow sphere acquires a marvellous proficiency. Or, to use the technical language of science, in order to advance there must be aggregation of mass, differentiation of structure, and specialization of function. Evidently, however, if there is an aggregation of mass, some of the mass is liable to be so far removed from the supply of oxygen, and the space into which carbon dioxide can be eliminated, that it is liable to be starved for the one and poisoned by the other. Nature adopted two simple ways to obviate this—first to form its aggregated masses in the form of a network or sponge, with intervening channels through which a constant stream of fresh water may be made to circulate, so that each individual cell of the mass could take its oxygen and eliminate its carbon dioxide with the same directness as its simple proto-type, the amoeba.

But in the course of evolution forms appeared with aerial respiration, and the insects, among these, solved the mechanical difficulty of respiration by a most marvellous system of air-tubes, or tracheae, extending from the free surface, and therefore from the surrounding air, to every organ and tissue. By means of this intricate network, air is carried and supplied almost directly to every particle of living matter. The respiration is not quite

direct with the insects, however, for the oxygen and carbon dioxide must pass through the membranous wall of the air tube before reaching or leaving the living substance.

In the next and final step, the step taken by the highest forms, the living material is massed, giving rise not only to animals of moderate size, but to the huge creatures that swarm in the seas or walk the earth, like the elephant. With all of these the step in the differentiation of the respiratory mechanism consists in the great perfection of lungs or gills, and in the addition of a complicated circulatory system with a respiratory blood, one of the main purposes being, as the name indicates, to subserve in respiration by carrying to each individual cell in the most remote and hidden part of the body the vital air, and in the same journey removing the poisonous carbon dioxide.

This has been called Indirect Respiration, because the living matter of the body does not take its oxygen directly either from air or water, but is supplied by a middleman, so to speak.

The complicated movements by which water is forced over the gills, or by which the lungs are filled and emptied, and the great currents of blood are maintained—that is, the striking and easily observed phenomena of respiration—are thus seen to be only superficial and accessory, only serve as agents by which the real and the essential processes, that go on in silence and obscurity, are made possible.

So far I have attempted to give a brief résumé of the views on respiration that have been slowly and laboriously evolved by many generations of physiologists, each adding some new fact or correcting some misconception, and I trust that this brief sketch has recalled to your minds the salient facts in our knowledge of respiration, and that it will give a just perspective, and enable me, if I may be permitted, to briefly describe what I believe to be my own contribution to the ever accumulating knowledge of this subject.

In 1876-77, Prof. Wilder, who may be said to have inherited his interest in the ganoid fishes directly from his friend and teacher, Agassiz, who first recognized and named the group, was investigating the respiration of the forms *Amia* and *Lepidosteus*, common in the great lakes and the western rivers. As his assistant it was my privilege to aid in the researches, and to acquire the spirit and methods, as in no other way is it so readily possible, by following out, from the beginning to its close, of an investigation carried on by a master. The results of that investigation were reported to this section in 1877, and formed a part of the proceedings for that year. From that time till the present the problems of respiration in the living world have had an ever increasing fascination for me, and no opportunity has been lost to investigate the subject. The interest was greatly increased by the discovery that a reptile—the soft-shelled turtle—did not conform to the generalizations in all the treatises and compendiums of zoology, which state with the greatest definiteness that all reptiles, without exception, are purely air-breathing, and throughout their whole life obtain their oxygen from the air and never from the water. The American soft-shelled turtles, at least, do not conform to this generalization, but on the contrary, naturally and regularly breathe water like a fish, as well as air like an ordinary reptile, bird, or mammal.

In carrying on the investigation of the respiration of the turtle, there appeared for solution the general problem, which, briefly stated, is as follows: In case an animal breathes both air and water, or more accurately, has both an aerial and an aquatic respiration, like the ganoid fishes, *Amia* and *Lepidosteus*, like the soft-shelled turtles, the tadpoles, and many other forms, what part of the respiratory process is subserved by the aqueous and what by the aerial part of the respiration? So far as I am aware this problem had not been previously considered. It was apparently assumed that there were in these fortunate animals two independent mechanisms, both doing precisely the same kind of work—that is, each serving to supply the blood with oxygen and to relieve it of carbon dioxide, as though the other was absent. That was a natural inference, for with many forms the respiration is wholly aquatic, all the oxygen employed being taken from the water, and all the carbon dioxide excreted into it. On the other hand, in the exclusively air-breathing animals, as birds and mammals, the respiration is exclusively aerial.

This natural supposition was followed in the first investigations on the respiration of the soft-shelled turtles, and while it was proved with incontestable certainty that they take oxygen from the water like an ordinary fish—that is, have a true aquatic

respiration, in addition to their aerial respiration—there was altogether too much carbon dioxide in the water to be accounted for by the oxygen taken from it. Furthermore, upon analyzing the air from the lungs of a turtle that had been submerged some time the oxygen had nearly all disappeared, and but very little carbon dioxide was found in its place, while, as compared with human respiration, for example, a quantity of carbon dioxide nearly as great as that of the oxygen which had disappeared should have been returned to the lungs. Likewise in Professor Wilder's experiments with *Amia*, to use his own words: "Rather more than one per cent of carbon dioxide is found in the normal breath of the *Amia*, but much more of the oxygen has disappeared than can be accounted for by the amount of carbon dioxide." Everything thus appeared anomalous in this mixed respiration, and instead of a clear, consistent, and intelligible understanding of it, there seemed only confusion and ambiguity. Truly these seemed like "bad experiments."

It became perfectly evident that the first step necessary in clearing the obscurity was to separate completely the two respiratory processes, to see exactly the contribution of each mechanism to the total respiration. But this was no easy thing to do. In the first place, the animal must be confined in a somewhat narrow space in order that air and water, which are known to have been affected by its respiration, may be tested to show the changes produced in it by the respiratory process, in the second place, the water has so great a dissolving power upon carbon dioxide that even if it were breathed out into the air it would be liable to be absorbed by the water. Then some means must be devised to prevent the escape of the gases from the water as their tension becomes changed, and, finally, the animal in the water must be able to reach the air. A diaphragm must be devised which would prevent the passage of gases between the air and the water, and at the same time offer no hindrance to the animal in projecting its head above the water. As a liquid diaphragm must be used, it occurred to me that some oil would serve the purpose, but the oil must be of peculiar nature. It must not allow any gases to pass from air to water, or the reverse, it must not be in the least harmful or irritating to the animal under experimentation, and, finally, it must itself add nothing to either air or water. Olive oil was thought of, and later the liquid paraffins. The latter were found practically impervious to oxygen and fulfilled all the other requirements, but unfortunately they absorb a considerable quantity of carbon dioxide. Pure olive oil was finally settled upon as furnishing the nearest approximation to the perfect diaphragm sought.

The composition of the air being known, and a careful determination of the dissolved gases in the water having been made, the animal was introduced into the jar and the water covered with a layer of olive oil from ten to fifteen millimetres thick. The top of the jar was then lashed, and a piece of plate glass pressed down upon it, thus sealing it hermetically. Two tubes penetrate this plate glass cover, one connecting with the overlying air-chamber and the other extending into the water nearly to the bottom of the jar. As the water and air are limited in quantity, the shorter the time in which the animal remained in the jar the more nearly normal would be the respiratory changes, the experiment was continued only so long—one or two hours—as was found necessary to produce sufficient change in the air and the dissolved gases of the water to render the analyses unmistakable.

Proceeding with the method just described, the results given in the following table were obtained—

Table of Mixed Respiration, showing the number of cubic centimetres of oxygen removed from air and water, and the amount of carbon dioxide added to the air and the water

	Oxygen		Carbon Dioxide	
	from air	from water	to air	to water
Ganoid Fish ( <i>Amia calva</i> )	65	10	22	53
Tadpoles ( <i>Larval Batrachia</i> )	70	5	24	51
Soft-shelled Turtle ( <i>Apudamutica</i> )	31	8	10	29
Bull Frog ( <i>Rana catesbeiana</i> )	183	4	110	77

NOTE.—The oxygen from both the water and the air, and the carbon dioxide in the air, were determined with exactness in all the experiments, but owing to the failure of some steps in the titration for the carbon dioxide in the water, the figures given for the *Amia* and the soft-shelled turtle are the calculated results, assuming that the respiratory quotient is one, as that is the relation found by analysis in the other cases.

\* See Wm. Thurner on the use of olive oil for the prevention of the absorption of carbon dioxide. *Repertorium der analytischen Chemie*, 1889, pp. 15-17.

It requires but a glance at the figures in this table to see that the aerial differs markedly from the aquatic part of the respiration. Even in the frog, in which the skin forms the only aquatic respiratory organ, the tendency is marked. The law appears to be unmistakably this, viz that in combined aquatic and aerial respiration, the aerial part is mainly for the supply of oxygen and the aquatic part largely for the excretion of carbon dioxide. This law, which I stated in 1886, has been confirmed by the repetition of old experiments and by many new ones made during the present summer. It is also confirmed by the experiments made on *Lepidosteus* in a different way by Dr. B. L. Mark, and published in 1890. I therefore feel that this is the expression of a general law in nature.

From the standpoint of evolution we must suppose that all forms originated from aquatic ancestors, ancestors whose only source of oxygen was that dissolved in the water. As the water is everywhere covered with the limitless supply of oxygen in the air, there being 209 parts of oxygen in 1000 parts of air as contrasted with the 6 parts of oxygen dissolved in 1000 parts of water, it is not difficult to conceive that in the infinite years the animals found by necessity and experience that the needed oxygen was more abundant in the overlying air, and that some at least would try more and more to make use of it. And as any thin membrane with a plentiful blood supply may serve as a respiratory organ to supply the blood with oxygen, it is not impossible to suppose that such a membrane, as in the throat, could modify itself little by little with ever increasing efficiency, and that a part might become especially folded to form a gill and another might become vascular or lung-like to contain air. While I am no believer in the purely mechanical physiology which sees no need of more than physics and chemistry to render possible and explain all the phenomena of life, yet it is patent to every one that, although vital energy is something above and beyond the energies of physics and chemistry, still it makes use of these, and certainly deal matter forms the material from which living is built. So given a living thing, it, in most cases, moves along lines of least, rather than of greatest, resistance, therefore if practically a limitless supply of oxygen may be obtained from the air and only a limited amount from the water, if anything that might serve as a lung is present, most naturally it (the animal) will take the oxygen from the air where it is in greatest abundance and most easily obtained. On the other hand, carbon dioxide is so soluble in water that practically a limitless amount may be exhaled into it, and as it is apparently somewhat easier, other things being equal, for it to pass from the liquid blood to the water than to the air, it seems likewise natural that the gills should serve largely for the excretion of the carbon dioxide into the water. This is the actual condition before us in these, and I believe in all other cases, of mixed or of combined aerial and aquatic respiration. And I believe, as stated above, that it may be laid down as a fundamental law in respiration that wherever both water and air are used with corresponding organs—gills for one and lungs for the other—that the aerial part of the respiration is mainly for the supply of oxygen, and the aquatic part largely for the getting rid of carbon dioxide.

It is not difficult to see in an actual case like that of the Ganoid Fishes (*Amia* and *Lepidosteus*) the logical steps in its evolution, by which this most favourable condition has been reached. A condition rendering these fishes capable of living in waters of almost all degrees of purity, and thus giving them a great advantage in the struggle for existence. But what can be said of the soft-shelled turtles, animals belonging to a group in which purely aerial respiration is almost exclusively the rule? Standing alone, this might be exceedingly difficult or impossible of explanation. The *Batrachia* (frogs, toads, salamanders, &c.) all have gills in their early or larval stage, and most of them develop in the water, and are in the beginning purely aquatic animals. The adults must therefore, in most cases, repair to the water at the spawning season and frequently in laying the eggs they must remain under the water for considerable intervals. Being under the water, and the need of oxygen becoming pressing, there seems to be, by a sort of organic memory, a revival of the knowledge of the way in which respiration was accomplished, when, as larvae, their natural element was water, and they take water into the mouth and throat. This may be done by as highly a specialized and purely aerial form as the little brown tree-frog (*Hyla pickeringsii*) or the yellow spotted salamander (*Ambystoma punctatum*). Another very interesting form, the vermillion-spotted newt (*Desmognathus*), after two or

three years of purely aerial existence goes to the water on reaching maturity and remains there the rest of its life, regularly breathing both by its lungs and by taking water into its mouth and throat. A still more striking example is given by Prof. Cope. The young siren almost entirely loses its gills, and later regains them, becoming again almost completely aquatic in its habits as in the larval stage.

With these examples, which may be seen by any one each recurring year, is it impossible or difficult to conceive that in the struggle for existence the soft-shelled turtles found the scarcity of food, the dangers and hardships on the land greater than those in the water? Or, remaining constantly in the water, and advantageously submerged for most of the time, it gradually reacquired the power of making use of its pharyngeal membrane for obtaining oxygen from the water and excreting carbon dioxide into it as had its remote ancestors. And further, is it not intelligible that with capacious lungs, which it can fill at intervals with air containing so large a supply of oxygen that it, like the other double or mixed breathers, should use its lungs to supply most of the oxygen and its throat to get rid of much of the carbon dioxide?

Indeed it seems to me that if the evolution doctrine is a true expression of the mode of creation, then development may be in any direction that proves advantageous to an organism, even if the development is a reacquirement of long discarded structures and functions.

In closing may I be permitted to say to the older biologists—to those familiar with the encouragements and inspirations that come with original investigation, that I trust they will pardon what to them is unnecessary personality or excess of detail in this address, for the sake of the younger ones among us, to whom the uphill road of research is less familiar. Judging from my own experience in listening to similar addresses by my honoured predecessors, it is helpful to know, when one is beginning, something of the "dead work," the difficulties and discouragements, as well as the triumphs, in the advancement of science.

#### MINES AND MINING AT THE CHICAGO EXHIBITION

THE exhibition of objects relating to mines and mining at the "World's Fair" promises to be one of exceptional interest and importance. The following details about it were given by Mr. George F. Kunz in a paper read before the recent meeting of the American Association for the Advancement of Science—

The building of mines and mining, which is entirely complete, is 700 feet long and 350 feet wide, at an elevation of 25 feet above the main floor. On both sides is a gallery 60 feet wide, running the entire length of the building. Up to the present time there have applied for space in this building 26 foreign Governments and 36 States, these exhibits to be supplemented by other State and Government exhibits, such as that of Sweden in the Swedish building, the East Indian in the East Indian court, Illinois in their State building, &c.

There will be a scientific collection of all the known elements, and with them a complete collection of all the known alloys of gold, silver, copper, zinc, tin, &c., such as electrum, German silver, Babbitts metal, fusible metal, and the thousand and one other, common and rare, used in the arts and industries. In the name of the Lake Superior copper mines, Prof. Alex. Agassiz has promised a complete exposition of ores, rocks, and processes, illustrating the occurrence mining, metallurgy of copper. There is now in preparation a coal collection to contain all varieties of coal, from every known occurrence in the United States. Petroleum will be shown as it never has been at any exhibition. The subject of abrasives of all kinds will form a special exhibit under the charge of Mr. T. Dunkin Paret, who has devoted his entire life to this subject, and is now making a special European trip to enlist the cooperation of foreign manufacturers and investigators to supplement the American exhibit.

The De Beers Mining Company of South Africa, who own and control more than 95 per cent of the entire diamond output, will make first a full and comprehensive exposition of diamond mining and the original blue stuff, a decomposed peridotite, enclosing carbonaceous shale, the matrix of the diamond, in great quantities. They will show it passing through

the various washing machines, and every process separating the diamond from the matrix, in which exists a percentage of 1 carat 205 milligrams in a load of 1600 pounds. There will be a case containing over 10,000 carats of diamonds of all colours and of the various qualities, with a full series of the associated minerals and rocks. Every stage of the cutting and polishing of the diamond will be represented.

Nearly every mineral dealer in the United States has applied for space, and from the foreign trips and other preparations it is very evident that in the line of cabinet specimens and educational minerals the assembled collections will exceed those of any other exposition in importance.

One of the large gallery halls will contain a reference library for the use of visitors. This it is hoped will be a very comprehensive exposition of the literature of the subject of mines, mining, geology, and mineralogy. This is to be supplemented by historical portraits, documents, and other allied material.

An early history of mining and mining processes will be shown, starting with stone hammers and other aboriginal implements found in the copper mines of Lake Superior and the turquoise mines of New Mexico, the old Mexican Pateo, to the most improved modern methods, and the remarkable sectional and glass models of mines, prepared by eminent mining engineers, used in the great mining lawsuits to prove their arguments.

One of the large corridor rooms in the gallery has been offered to the American Institute of Mining Engineers for their own use as a headquarters during the Exposition. They in turn may extend the courtesy to mechanical and civil engineers, as well as the English, German, French, and other foreign engineers whose hospitality they enjoyed in 1889. There is every reason to believe that at least from 800 to 1000 foreign engineers will visit the Exposition.

If only three fourths of the promised exhibits are received, and there is every assurance that there will be many more coming, it may be safely said, even now, that the mining, metallurgical, geological, and mineralogical exhibits of the Columbian World's Fair will exceed in scientific importance and in extent the combined exhibits of the Centennial, the 1878, 1889, the Paris and the Vienna Expositions, at least two fold.

### UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Lord Walsingham, the High Steward of the University, has expressed his wish to give annually for three years a gold medal for the best monograph or essay giving evidence of original research in any subject coming under the cognizance of the Special Board for Biology and Geology. The offer having been accepted and the regulations for the medal having been approved, the Special Board for Biology and Geology give notice that the medal is offered for competition for the second time during the ensuing academical year. The essays are to be sent to the chairman of the Special Board (Prof. Newton, Magdalene College) not later than October 1, 1893.

The regulations for the medal are published in the *Cambridge University Reporter*, No. 908 (November 17, 1891), p. 186.

Sir R. S. Ball, Loundean Professor, will give his inaugural lecture in the Anatomical Theatre on Friday, October 21, at noon.

Dr. Cayley, Sadlerian Professor of Mathematics, resigns his place on the Council of the Senate on October 25.

The Council of the Senate recommend that the University of the Cape of Good Hope should be affiliated to Cambridge, on the same terms as those granted to New Zealand.

LONDON.—Four lectures upon "The Sun in its Relation to the Universe of Stars" will be delivered in Gresham College, at six p.m. on the evenings of October 25, 26, 27, and 28, 1892, by the Rev. Edmund Ledger.

### SCIENTIFIC SERIALS

*The Journal of the Royal Agricultural Society of England*, 3rd Series, Vol. III, pt. 3.—Allotments and Small Holdings, by Sir J. B. Lawes and Dr. Gilbert. The authors have collected statistics relating to Allotments and Small Holdings in Great Britain. They point out that "within the present century there has been a great reduction in the number both of

owners and of occupiers of farms not exceeding 50 acres in area, such as it seems to be the object of the promoters of the Small Holdings Act of 1892 greatly to increase." After noticing the Rothamstead Allotments they proceed to discuss the conditions essential to the success of small holdings, and they conclude that ordinary rotation farming is much less suitable for small holdings than dairy farming, the production of poultry and eggs, and market gardening when favourable conditions exist, the authors do not believe, however, that the system of small holdings will materially check the influx of agricultural labourers into the towns. This number of the *Journal* also contains a short article by W. H. Hall on Small Holdings in France. Mr. Hall is "convinced that small holders (in England) have a great future before them as soon as they can be educated up to producing such articles as require to be consumed fresh, and will not bear long carriage." This last clause contains the key of the whole matter.—On the Vermin of the Farm, pt. II, by J. E. Harting. In this paper the author has much to say in defence of the mole (*talpa europæa*), and of the weasel (*mustela vulgaris*), there is little but condemnation, however, for the hedgehog, the stoat, and the polecat, the last mentioned animal is now hardly known to most people, though the domesticated variety (the ferret) is common.—The Warwick Meeting of 1892, by Dr. Fream, Official Reporter. This report shows the meeting to have been a good average one, except in the attendance of visitors on the last two days. Judge's reports show that in many cases the quality of the exhibits of live stock was far above the average.—Miscellaneous Implements Exhibited at Warwick, by T. H. Thurstfield.—The Farm Prize Competition of 1892, by J. B. Ellis.—Among the shorter articles is one deserving of careful attention, entitled New Modes of Disposing of Fruit and Vegetables, by Chas. Whitehead, in which are discussed the "evaporating" and the "canning" of fruit, methods already in use in Queensland are described and discussed with reference to their adoption in this country when prices for fresh fruit are low.—Dr. J. W. Leather contributes a short article upon his method of detecting and estimating "castor-oil seeds in cattle foods." A weighed quantity of the suspected food is digested with hot dilute sulphuric acid (or HCl, about 2 p.c.) for half an hour, washed free from acid, re-digested with a hot dilute solution of caustic soda, washed, and then finally treated with a quantity of bleaching powder. The husks of all seeds other than castor oil seeds are bleached by this treatment, and any unbleached husks can be picked out and weighed.

*Wiedeman's Annalen der Physik und Chemie*, No. 9.—The principle of least effect in electrodynamics, by H. von Helmholtz.—On the differences of potential of chains with dry solid electrolytes, by W. Negbauer.—On the reciprocity of electric osmose and flow currents, by U. Særen.—Resonance phenomena and absorptive capacities of metals for the energy of electric waves, by V. Bjerknes.—Objective presentation of the Hertzian experiments with rays of electric force, by L. Zehnder.—Dispersion and absorption of light according to the electrical theory of light, by D. A. Goldhammer.—On the measurement of high temperatures, by L. Holborn and W. Wien. The apparatus was a modification of Le Chatelier's thermo-element, consisting of a combination of platinum and a platinum-rhodium alloy. This was calibrated by placing it inside the porcelain vessel of an air-thermometer and comparing the readings, different thermo-couples were compared by exposing together in short porcelain tubes, two branches being welded together. The following fusing temperatures were deduced: gold 1072°, silver 968°, copper 1082°.—On the expansion of gases at low pressures, by G. Meißner. Working with pressures ranging from 770 to 4 mm, and temperatures from 0° to 100°, the gases being kept at constant volume, the supposed law of constant decrease of coefficient of expansion with decreasing pressure was found not to hold good. That of air decreases down to 232 mm, where it is 0.003659, and then increases. That of carbon dioxide decreases down to 76 mm, after which it increases, whilst that of hydrogen increases steadily.—Specific gravity and heat of fusion of ice, by J. v. Zakrzewski. The apparatus was a very delicate form of Bunsen's ice calorimeter. The specific gravity of ice at -0.701°C was found to be 0.916710. The cubical coefficient of expansion at that temperature was 0.000077, which gives for the sp. gr. of ice at 0°C the value 0.916660.—On the theoretical conceptions of Georg Simon Ohm, by K. Von der Mühl.—Variation of the specific volume of sulphur with the temperature, by M. Toepler.

## SOCIETIES AND ACADEMIES

## LONDON

Royal Society, June 16—"Thermal Radiation in Absolute Measure" By Dr J T Bottomley, M A, F R S

The paper contains an account of an experimental investigation by the author in continuation of researches on the same subject which have been already published (Roy Soc Proc, 1884, and Phil Trans, 1887). In the earlier experiments metallic wires heated by an electric current were used. The loss of heat from a heated body, however, depends to some extent on the form and dimensions of the body, and it seemed important to experiment on the loss of heat from bodies differing in form from the wires already used, and larger in dimensions.

Accordingly, two copper globes used by Mr D Macfarlane in 1872 (Roy Soc Proc, 1872, p 93) were employed for a new series of experiments.

After preliminary experiments (using the same enclosure which Macfarlane employed and with the surfaces of Macfarlane's globes prepared in four different ways) new apparatus was constructed. The object was to experiment both with full air pressure and with different amounts of exhaustion of the air, and Macfarlane's enclosure is unsuitable for this purpose.

In the arrangement adopted, the heated globes were hung at the centre of a hollow metallic sphere, which was connected with the Sprengel pump and surrounded with cold water, and were allowed to cool. The temperature of the cooling globe was read off at equal intervals of time by means of a thermoelectric junction, and from these readings the absolute loss of heat per unit of cooling surface, per unit difference of temperatures of surface and surroundings, per unit of time, is calculated.

The details of the apparatus and method of experimenting are given in the paper. It is enough to say here that the globes were used with their surfaces in two different conditions—(1) Thinly coated with lamp-black, and (2) silvered and brightly polished, and in both conditions the absolute loss of heat, both in air and in vacuum more or less complete, was determined. The tables and curves attached to the paper give the details of the results.

To quote one or two examples—With the sooted surface a total loss of heat by convection and radiation of  $3.42 \times 10^{-4}$  c g s units per square centimetre, per second, per  $1^\circ$  C of difference of temperatures of globe and surroundings, was observed with a difference of temperatures of  $100^\circ$  C, and with the surroundings at about  $14^\circ$  C. Under similar circumstances the radiation in vacuum of  $\frac{1}{2}$  M (half a millionth of atmospheric pressure of non-collapsible gas) was about  $1.40 \times 10^{-4}$ .

Taking a silvered and brightly-polished surface under the same circumstances, the loss in full air was  $2.30 \times 10^{-4}$  c g s, and with the highest vacuum and brightest polish obtained, it was reduced  $1.80 \times 10^{-6}$ , with in this case a difference of temperatures of  $180^\circ$  C. The loss with  $100^\circ$  C difference would be considerably less, but is not known experimentally at present.

The author returns thanks to Mr James H Gray, M A, B.Sc., for excellent assistance given, and expresses himself most deeply indebted, both for assistance in experimenting and calculating of the results, and for most valuable and ingenious aid of various kinds during the course of this work, to his friend Mr A Tanakadate, now Professor in Tokio, Japan.

Entomological Society, October 5. Henry John Elwes, vice-president, in the chair.—Mr C O. Waterhouse exhibited a specimen of *Iatridius nodifer* feeding on a fungus, *Trichosporium roseum*.—Mr McLachlan, F R S, exhibited a male specimen of *Elenchus tenuicornis*, Kirby, taken by the Rev A E Eaton, on August 22 last, at Stoney Stoke, near Shepton Montague, Somerset, and described by him in the *Entomologist's Monthly Magazine*, October 1892, pp. 250-253. Mr McLachlan stated that another specimen of this species had been caught about the same date in Claygate Lane, near Surbiton, by Mr Edward Saunders, who discovered that it was parasitic on a homopterous insect of the genus *Liburnia*, and had also described it in the *Entomologist's Monthly Magazine*.—Mr J M Adye exhibited, for Mr. McKee, a large collection of *Colias edusa*, *C. edusa* var. *helice*, and *C. hyale*, all taken in the course of five days' collecting in the neighbourhood of Bournemouth and Christchurch, Hants. There were twenty-six specimens of *helice*, some of which were remarkable both in size and colour. He stated that Mr McKee estimated the proportion of the variety

*helice* to the type of the females as one in fifty. Mr. Adye also exhibited two specimens of *Deiopea pulchella*, recently taken near Christchurch. Mr Hanbury, Mr Jenner Weir, and Mr Merrifield commented on the interesting nature of the exhibition and on the recent extraordinary abundance of *C. edusa* and the var. *helice*, which was probably not exceeded in 1877.—Mr Dillas Beeching exhibited four specimens of *Plusia moneta*, lately taken in the neighbourhood of Tunbridge Wells.—Mr H Goss exhibited, for Mr Gervase F Mathew, two *Plusia moneta* and their cocoons, which were found at Frimsted, Kent, on September 3 last. It was stated that Mr Mathew had found seven cocoons on the under side of the leaves of monkshood, but that the imago had emerged from five of them.—Mr Rye exhibited a specimen of *Zygena filipendule* var. *chrysanthemi*, and two varieties of *Aictia villia*, taken at Lancing, Sussex, also varieties of *Coccinella ocellata* and *C. oblongoguttata* from Oxshott.—Mr A H Jones exhibited specimens of *Argynnis palea* var. *var.*, and var. *aridache*, the females of which showed a tendency to melanism, recently taken in the Upper Engadine, also melanic forms of *Erebia melampus*, and a specimen of *Erebia nina*.—Mr Elwes exhibited specimens of typical *Erebia melas*, taken by himself in the Western Tyrol, on July 25 last, at an elevation of 7000 feet, also specimens of the same species from Hungary, Greece, and the Eastern and Central Pyrenees. He stated that the absence of this species from the Alps, which had seemed to be such a curious fact in geographical distribution, had been first disproved by Mrs. Nicholl, who discovered it at Campiglio two years ago. He also exhibited fresh specimens of *Erebia nina*, taken at Riva, on the lake of Garda, at an elevation of about 500 feet, also specimens of the same species, taken at the same time, at an elevation of about 5000 feet, in cool forest glades, and remarked that the great difference of elevation and climate did not appear to have produced any appreciable variation in this species.—Mr G T Porritt exhibited two varieties of *Abana nigrovarians*, bred during the past summer from York larva. Also a curious Noctua taken on the sandhills at St Anne's-on-Sea on August 20 last, and concerning which a difference of opinion existed as to whether it was a melanic form of *Agrotis curvator* or of *Caradrina cubicularis*. Also a small dark form of *Orygia antiqua*, which had occurred in some numbers at Longridge, near Preston.—Mr A Eland Shaw exhibited a specimen of *Meioctethus grossus*, Linn, taken lately at Irstead, in the Norfolk-broad district. He stated that this was the first recorded capture of this species in Britain since 1884.—Mr C G. Barrett exhibited a specimen of *Syrictthus alveus*, caught in Norfolk about the year 1860, a beautiful variety of *Argynnis euphrosyne*, caught this year near Godalming, and a series of varieties of *Ennomus angularia*, bred from a female taken at Nunhead.—Mr P Crowley exhibited a specimen of *Zygena filipendule* var. *chrysanthemi*, taken last August at Riddlesdown, near Croydon.—Lord Walsingham, F R S, sent for exhibition several specimens of larvæ of *Sphinx pinastri*, preserved by himself, which were intended for presentation to the British Museum. The larvæ had been sent to him by Lord Rendlesham, who obtained them from ova laid by a female captured in Suffolk last August.—M de Nicéville communicated a paper entitled "On the variation of some Indian Euploas of the subgenus *Stictophea*" and Captain E Y Watson exhibited, on behalf of M de Nicéville, the specimens referred to in this paper. Colonel Swinhoe, Mr Hampson, Mr E B Poulton, F R S, and the chairman took part in the discussion which ensued.—Mr W Bateson read a paper entitled "On the Variation in the Colours of Cocoons and Pupæ of Lepidoptera, further Experiments."—Mr Poulton read a paper entitled "Further Experiments upon the Colour relation between certain Lepidoptera and their Surroundings."—Miss Lilian J Gould read a paper entitled "Experiments on the Colour-relation between certain Lepidopterous larvæ and their surroundings, together with observations on Lepidopterous larvæ." A long discussion ensued, in which Mr Jenner Weir, Dr Sharp, F R S, Mr Merrifield, Mr Poulton, and the chairman took part.

## PARIS

Academy of Sciences, October 10. M Ducharte in the chair. M Emile Picard presented to the Academy the second volume of his "Traité d'analyse."—The University of Padua invited representatives of the Academy at the forthcoming tercentenary celebration of Galileo's accession to his chair at that University.—A decisive blow to the theory of centripetal and ascending motion in cyclones, by M H Faye.—The move-

ments of the heart, studied by chronophotography, by M Marey. The heart of a tortoise was removed and mounted so that a funnel led into an auricle, and a bent tube out of the ventricle and upwards to the mouth of the funnel. The funnel was filled with defibrinated blood, which passed into the auricle and thence into the ventricle. When the latter was full, an automatic systole projected the blood upwards through the tube and back into the funnel. This process was repeated for several hours after death. It was more minutely studied by taking a series of instantaneous photographs in rapid succession (reproduced), which show the details of the process with great accuracy. For actinic purposes, the heart was painted white with water colour. The hypothesis of an active diastole of the ventricle was proved to be unfounded.—The inhibitory phenomena of the nervous shock, by M H Roger.—On the transformation of the equations of Lagrange, by M Paul Painlevé.—On a class of curves and surfaces, by M A Pellet.—On the motion of a thread in space, by M G Floquet.—On internal reflection in crystals, by M Bernard Brunhes.—A new method of preparation and photometry of the phosphorescent sulphide of zinc, by M Charles Henry. It is possible to obtain several pounds at a time of a fine phosphorescent zinc sulphide by the following process: Add ammonia to a perfectly neutral solution of pure zinc chloride, redissolve the precipitate in an excess of ammonia, precipitate completely, but without the slightest excess, the ammoniacal oxide of zinc by sulphuretted hydrogen, heat to a white heat in a crucible of refractory earth placed inside a graphite crucible, after having well washed and dried the amorphous sulphide to the exclusion of all impurities. By Mascart's photometer, the intensity of light emitted by a sample of the sulphide in candle metres after saturation was 0.000215. But this value is probably too small.—On the antimonites of pyrogallol, by MM H Causse and C Bayard.—On the tartaric ethers, by M P Freundler.—Volumetric determination of the alkaloids, by M L Barthe.—On a new method of brick manufacture, used in certain parts of Central Asia, by M Edouard Ilanc. This mode of manufacture is practised by the tribes in Western Mongolia, on the frontier of Siberia. The extremes of temperature render a brick of great durability a necessity of life. This is attained by the use of steam. The oven is cylindrical and surmounted by a hemispherical cap, which is kept open for the first three days. The bricks, about 7000 at a time, are baked by means of a fire fed by about 7000 kgr of an annual ligneous plant, the *Alhagi Camelorum*. On the third day, the opening is closed with felt, which is kept constantly wetted, so that the bricks are enclosed in a steam bath, while kept at a red heat. Under these circumstances, some novel chemical reactions appear to take place. The bricks, red after the first period, appear dark grey after the second part of the process. Their structure appears porous, they become sonorous and acquire a great hardness. They show a striking resemblance to certain trachytes. Made from the same clay as our bricks, they resist weathering very much better, and have an extraordinary hardness and cohesion.—A process for testing the purity of coprah oils and palm oils, by M Ernest Milliau.—On the part played by spermine in intra-organic oxidations, by M Alexandre Poehl.—On the respiration, transpiration, and dry weight of leaves developed in sunlight and in the shade, by M L Geneau de Lamarlière.—On the structure of the assimilating tissue of the branches in Mediterranean plants, by M William Russell.—Experimental study of the action of the humidity of the soil on the structure of branches and leaves, by M Auguste Oger.—Contributions to the stratigraphy of the Pyrenees, by MM Roussel and De Grossouvre.—On some bombs of Etna, from the eruptions of 1886 and 1892, by MM L Duparc and L Mrazec.—Meteoric iron recently fallen at Hassi Lekna, in Algiers, by M Stanislas Meunier.—Oceanographic observations relating to the basin of Arcachon (Gironde), by M J Thoulet.—Vegetation of the lakes of the Jura mountains, by M G Rambault Ant Magnin.—M Buschoffsheim, on behalf of Prof Welneck, Director of the Prague Observatory, presented a photograph of the lunar crater Vendelinus.

## POLAND'S "FUR-BEARING ANIMALS"

*Fur-bearing Animals in Nature and Commerce* By Henry Poland, F.Z.S., 1 vol, 8vo (London Gurney and Jackson, 1892)

ALTHOUGH, as civilization spreads with ever-quickening progress over all parts of the world's surface, wild animals necessarily diminish in numbers year by year, few people have any idea of the enormous quantities of furs and pelts still annually imported into the United Kingdom, and of the extent of the commerce in such commodities still carried on. Mr Poland's useful treatise on Fur-bearing Animals will afford us much information on this subject. In the introduction to his volume full statistics about the past and present condition of the fur-trade are given, and it is stated that at the great fur sales now held at the College Hill sale-rooms in London the annual value of all classes of fur-skins sold is little short of £1,000,000.

But it is with the main portion of the present work that naturalists will be most interested, as, so far as we know, this is the first occasion on which a large amount of practical knowledge of the subject has been combined with a certain amount of scientific information. Mr Poland takes the fur-bearing animals systematically, mostly, it appears, according to the order and nomenclature employed in the list of animals in the Zoological Society's Gardens, and gives us under each head particulars as to their localities, distribution, coloration, and varieties, together with information as to the quantities of skins imported and the uses to which they are devoted.

Beginning with the Quadrumana, we find that the skins of about twenty five Monkeys and Lemurs are used in commerce. Of these the most abundant is the "Black Monkey" of Western Africa (*Colobus vellerosus* and other allied species), of which some 90,000 are imported every year. Another species of *Colobus*, the *Guerza* of Abyssinia and Eastern Africa, also furnishes a "rare and much esteemed skin," of which the value is from 10s to 15s. We may remark that the Tcheli Monkey (*Macacus tcheliensis*) is not from Cochin China, as stated by Mr Poland, but from Manchuria, north of Pekin, where it ranges further north than any other Monkey now existing. There is a fine example of this species at present living in the Zoological Society's Gardens. The "China Grey Monkey," described as having a "long white tail," is evidently of quite a different species, the Tcheli Monkey having only a very short caudal appendage.

The Carnivora, which next follow, take up the greater part of Mr Poland's volume, nearly 150 species of this extensive group supplying pelts which are more or less useful to mankind. Commencing with the larger Cats, our author calls attention to the great difference between the Bengal Tiger and the Mongolian or Chinese variety of the same animal, in which the fur is very thick, often from 1½ to 2 inches in length, and makes a long fringe round the face. Skins of the Chinese Tiger are much esteemed on this account, and fetch from £10 to £40 each, according to quality; whereas a good Bengal Tiger

skin may be purchased at about £4 or £5. The Lynx is another of the true Cat-tribe which furnishes a rather important article of trade, the quantity of Lynx-skins imported by the Hudson's Bay Company ranging up to 40,000, and in exceptional years reaching even to 70,000. Coming to the Musteline Carnivora or Weasels, we find the Mink (*Mustela vison*) an animal of still greater importance in trade. In 1890 upwards of 360,000 skins of the Mink from North America were sold in London, and converted mostly into muffs. On the other hand, an allied species of the same genus, the Ermine (*M. erminea*), formerly so much esteemed, and regarded as a princely fur to be devoted exclusively to royalty, is going quite out of fashion. "It has become very much neglected and a few years ago was practically unsaleable."

The fur of the Skunk, *Mephitis mephitis*, many persons will be surprised to hear, in spite of its "powerful scent," which "cannot be entirely got rid of," is largely used. In 1891 nearly 700,000 skins of it were imported, and worked up into muffs and capes. But the prince of furs of this division of the Carnivora is that of the Sea-otter, *Enhydra lutris*, of the north-west coast of America, an animal generally supposed to be almost extinct in consequence of long ages of persecution. But 2369 Sea-otter skins were imported by the Alaska Commercial Company and other traders in 1891, and sold at an average price of £57 apiece. "The fur is principally consumed in Russia, where it is used for collars of noblemen's coats."

From the Sea-otter we pass by an easy transition to the Fur-seals—a group still of sufficient importance to have brought three of the greatest nations of the world nearly to loggerheads, but in bygone years much more abundant than now. From South Georgia in the Antarctic Seas one million two hundred thousand Fur-seal-skins are said to have been taken soon after its discovery, and nearly an equal quantity from Kerguelen Island, but the natural consequence has followed that the animal has become practically extinct in the Antarctic seas. The only species of Otaria that still yields its skin year by year to supply the ladies of Europe and America with "sealskin jackets" is the Alaska Fur seal, *Otaria ursina*, which, owing to the stringent regulations enforced for its preservation, is still abundant in certain parts of the North Pacific. According to the best authorities about 4,500,000 of this Fur-seal resort to the Pribylov Islands every breeding season, and until 1890, when the number to be slaughtered was reduced, 100,000 were killed every year. Smaller quantities are obtained from other parts of the North Pacific. We need not here go into further details upon this animal which has lately been the subject of so much discussion, except to say that unless even more severe regulations are made for its preservation than those now existing, the Alaska Fur-seal will indubitably share the fate of its Antarctic brethren, and cease to furnish an article of commerce.

Of the order Insectivora, which follows the Carnivora, Mr. Poland only mentions two species as supplying fur for the use of mankind. These are the Common Mole (*Talpa europæa*) and the Russian Musk-rat or Desman (*Myogale moschata*). The skin of the Mole is so small as to be of little value, but several thousands are collected annually and converted into those most comfortable of garments, moleskin waistcoats. The fur of the

Russian Desman (*Myogale moschata*) is sometimes used in this country for mantle-trimmings, but is more appreciated in America. The Desman of the Pyrenees (*My. pyrenaica*), which Mr Poland confounds with that of Russia, is a much smaller and quite different animal.

We now come to the great group of Rodents, many of which supply their skins in enormous quantities for the benefit of mankind. Mr Poland's list contains thirty-three species of this Order. The Beaver, formerly of such pre-eminent importance, is now much reduced in numbers, but 63,419 Beaver-skins were sold by the Hudson's Bay Company in 1891. Another Canadian Rodent, the Musquash (*Fiber zibethicus*), still ranges over the "north-west" in enormous armies, from three to four millions of their skins being obtained every year. In 1891 the Hudson's Bay Company alone sold 554,104 of them. Another much appreciated little animal of the Rodent order is the Chinchilla from the highlands of Chili and Bolivia. Its fur, which is remarkably soft and delicate, is principally used in England, France, and America. Several allied species of the peculiar South American family *Chinchillidae* are also called by the general name of "Chinchilla."

Of the Leporidae or Hare family, which concludes the Rodents, the Polar Hare and the Common Rabbit supply the largest numbers of useful skins. Of the Russian or Polar Hare (*Lepus glacialis*)—one of the best-known denizens of Arctic latitudes—from 2,000,000 to 5,000,000 skins are said to be collected annually, mostly in their thick white winter coats. But Rabbit-skins are employed in much more enormous quantities. Since the great increase of this Rodent in Australia and New Zealand, where, as is well known, the Rabbit has become an awful pest, the number of its skins sent to London for sale from those colonies has increased year by year, until, according to Mr Poland's calculations, from fifteen to twenty millions are now imported. Very large numbers of Rabbit skins are also brought to England from France, Germany, and other countries, mostly taken from domestic varieties.

The American "Buffalo" (more correctly "Bison") is extinct as regards trade purposes, so that we need not go into the quantities of "Buffalo-robies" formerly imported, which in Catlin's time reached 200,000 in the year; nor will the other species of the order Ungulata, of which Mr Poland gives forty-six in his list as affording skins more or less used in commerce, detain us long. The most important of them are the different varieties of the domestic Sheep and Goat, which are spread all over the world and supply mankind with every variety of clothing-materials. The extent of this commerce is enormous. Of tanned Goatskins alone 7,259,212 were imported into this country in 1891, and 5,613,996 skins of "East Indian Sheep" were sold in London.

The Edentates, Marsupials, and Monotremes, with which Mr Poland concludes his volume, are of small importance after the preceding orders. "Australian Opossum," however, under which common name are included skins of several different species and varieties of the genus *Phalangista*, forms an exception, as the annual supply of this article exceeds two million skins, which are much appreciated for their "cheapness, light weight, pretty colour, and general usefulness." Of Kangaroos of all sorts over 120,000 skins were imported in

1891, so that, what with these and the Phalangiers and its twenty million Rabbit-skins, Australia has a fair share of this lucrative commerce. But altogether, no doubt, the Dominion of Canada and adjoining district of Alaska still get the lion's share of the traffic in "furs and pelts."

In concluding our somewhat lengthy notice of Mr Poland's volume we may say that it is replete with information that a zoologist cannot obtain elsewhere in a convenient form, but at the same time contains many errors in the identification of the species, some of which we have pointed out. In a second edition, which will doubtless be called for, the author should obtain the assistance of a scientific expert. He would also do well to cut out of his list some of the less important species (such as the Dingo, Great Anteater, and Echidna), which are not really used for trade purposes, and to bring up his statistical information under every head to the most recent date.

#### SPINAL NERVE—IMPULSES AND ELECTRO-MOTIVE CHANGES

*The Structure and Functions of the Brain and Spinal Cord.* By Victor Horsley, B.S., F.R.C.S., F.R.S. (Griffin and Co., 1892.)

AS stated in the preface, the present volume (being the Fullerton Lectures for 1891) discusses the spinal cord and ganglia alone, and is to be followed by two others, dealing respectively with the brain and with physiological psychology.

Most books of this character have to be considered in their relation to two classes of readers—those who are experts in its subject-matter and those who are not—a distinction that applies with special force to the outcome of Royal Institution lectures. We shall therefore take two readings of the volume before us.

The table of contents and a cursory glance at the text very soon bear out the author's modest remark that these lectures have no pretensions to form a monograph upon the subject of which they treat. Nor are they an elementary review of it (in the ordinary sense of these words), but rather a series of vignettes—historical, zoological, and speculative—relating to the nervous system. The historical lecture is interesting, the curious and hideous figure on p. 13, from a twelfth century manuscript in the Bodleian Library, very aptly fulfils its purpose, viz., to demonstrate that no advance is there apparent upon the ideas of Aristotle. Prof. Horsley avoids plainly asserting that Sir Charles Bell discovered the sensory and motor functions of the nerve-roots, the statement is implied, not made, at first reading we think it is made, on second reading we recognize that it is not made, on third reading that it is positively implied. It is evident that Prof. Horsley has read Bell's original pamphlet, "Idea of a New Anatomy of the Brain" (1811);<sup>1</sup> he does not, however, go

<sup>1</sup> Not an easy matter—we only know of one copy in London, that at the British Museum misdated 1802—nor a superfluous matter, as any one knows who has compared the "reprints" of 1824 and of 1830 with the original paper in the Phil. Trans. of 1821 on the nerves of the face. Correct reprints of Bell's first paper have been published in "Documents and Dates of Modern Discoveries in the Nervous System" (1 by A. Walker), London, 1839, and in the "Journal of Anatomy and Physiology" for 1860, by A. Shaw.

on to say that Bell's two roots (before 1824) were an anterior "cerebral" root, subserving motion and sensation, and a posterior "cerebellar" root serving to govern vital actions. The *principle* of localization in nerve-roots, far more clearly stated by Walker in 1809 and the facts demonstrated by Majendie in 1822, are not alluded to. In the second lecture Kleinenberg's cells are figured and described, and on the next page admitted to be mythical, thus Prof. Horsley is enabled legitimately enough to utilize this time-honoured if anatomically incorrect illustration to enforce the essentially correct principle of differentiation. Lecture III treats of jelly-fish, star-fish, and cray-fish, with reference to rhythm, "localization" and co-ordination of movements. "Localization" is used as a term to denote a physiological property or function (pp 48-49), *i.e.*, as used by psychologists to denote an act of the subject, rather than as used by physiologists to indicate observed relations between parts and functions. This use of the word is perfectly legitimate, but it is rather apt to create confusion of thought. "Localization" is sometimes used in a similar sense in relation to brain-function, and with a similar inconvenience. "Localization" by the brain in a psychological sense is properly localization by the subject, localization *in* the brain is an object of physiological experiment. No doubt it may be said that psychological localization rests upon physiological differentiation and localization, none the less the use of the term to denote a physiological property or function is not advisable without very careful definition. Lecture IV deals with vertebrates nerve-fibres, gullet theory of canalis centralis, spinal cord, and nerve-roots. Lecture V with ganglia. Here we must criticise. Looking to the class of readers addressed, Fig. 26 may be misleading as regards the anatomy of anterior and posterior roots. Fig. 28 (altered from Hirschfeld and Leveillé) is very confusing, and the anatomy of the brachial and lumbar plexuses is strange. A reader who should gather his notions of the functions of spinal ganglia from pp 110-113 would have a very wrong idea of the state of our physiological knowledge, nor does the odd expression, "the immense discovery by Claude Bernard, of the so-called vaso-motor system of nerves," possess much justification as regards historical accuracy.

The four last lectures contain—necessarily mingled with familiar elementary considerations—a statement of the results arrived at by Professors Gotch and Horsley from their electrical investigation of nerve-impulses in afferent and efferent nerve-channels, and to the expert form the most important part of the book. We begin, therefore, to read more closely, still bearing in mind, as indeed is suggested by the style, the requirements of non-expert readers. Nothing arrests attention on the first

two pages. On p 129 we pause at this sentence—*"It is very interesting to see that the protoplasm of a nerve conductor has a distinctly longitudinal arrangement, which, it is not going too far to suggest may, by virtue of this fact, be more adapted for the polarization of its molecules for the better transmission of nerve-impulses"*. Having dissected out the possible meaning of this sentence we proceed. Two pages further we are stopped for a moment by a confusion between the local excitability of nerve and its conductivity. On the next page (p 132) we demur to the assertion that "secondary tetanus depends upon the electrotonic state of the first preparation". On page 138 we find no reason to accept the distinction that "no doubt may reasonably exist that active nerve yields products of oxidation, which doubt certainly exists as to the acidification of nerve". Both facts are possible but unproven, no proof whatever has been attempted of the first, the second has been investigated with positive and with negative results. Page 146 includes a figure in which the current is *not* shown as an action current, but the reverse, moreover, with the instrument figured (capillary electrometer), *no current* is under observation.

But these twenty pages are enough, and we shall have but little space to discuss what forms the main positive differentia between Prof. Horsley's book and other books of the same class, *i.e.*, the conclusions derived from electrical data.

The conditions of criticism in this connection are altogether different, and we need not stop to examine into the accuracy of elementary points. Prof. Horsley is now addressing himself to an expert audience, his reasoning and his data have yet to pass through the refining fires of doubt and of objection, with, it is to be hoped, ultimate confirmation. The principle of the method of investigation is a well-established one, we know that electrical variations are indicators of functional variations, in the spinal cord, as elsewhere, functional activity may therefore be roughly gauged by galvanometer or by electrometer. Gotch and Horsley did this as regards efferent channels and afferent channels, as regards the first they found by the electrometer that the character of discharge in the pyramidal tract does not differ from its character in motor nerves, as regards the afferent tract they find that impulses pass up the cord chiefly in the posterior column of the same side. These conclusions may be admitted without imprudence. But the conclusions that may not safely be admitted without further experimental elaboration, are those relating to the functional discharges (inferred from electrical discharges) up and down the anterior and posterior roots, and to the quantitative distribution of centripetal impulses in the various columns of the cord. As regards this second point the physical conditions are not sufficiently analyzed (either in this volume or in the original paper) for us to admit, *e.g.*, the average galvanometric swings of 60 and 20 indicate a passage of afferent impulses in the proportions 60 and 20 per cent in the posterior and in the lateral columns respectively. That the deflection was proportional to the number of fibres excited, is an assumption requiring proof (p 212, *c/f* also pp 145, 159, 160).

As regards the first point, it was found that electrical discharges pass easily *down* as well as *up* the posterior

<sup>1</sup> In point of time Brown Séquard is the true discoverer of vaso-motor nerves. Bernard's experiments were made subsequently, and interpreted otherwise.

<sup>2</sup> D'après ces expériences, il n'est donc pas possible d'expliquer le réchauffement des parties par une prétendue paralysie des artères, qui, à raison d'un élargissement passif, laisseraient circuler une plus grande quantité de sang.

<sup>3</sup> Si alors (à la galvanisation) les artères, comme les veines, se resserrent et reviennent sur elles-mêmes, cela tient à ce qu'il n'y a plus de sang pour les distendre, mais ce n'est pas du tout l'effet d'un resserrement actif des vaisseaux.

<sup>4</sup> Il ne peut venir à l'idée de personne de penser à rapporter le phénomène circulaire qui succède à la section du nerf sympathique à une paralysie pure et simple des artères. Bernard, *Annales des Sciences Naturelles*, 1854, p. 198.

root, but are "blocked" *up* the anterior root, and diminished *down* that root. But in the inferences *qua* functional impulses derived from these data, two considerations appear to have been insufficiently borne in mind—(1) The rapid death of interrupting grey matter as compared with the endurance of white matter, and (2) the disproportionate magnitude of negative variations by *electrical* excitation as compared with negative variations by *functional* excitation. The contrast between interrupted and non-interrupted tracts, as regards the transmission, gauged electrically, may have been in part due to the first cause, and an adequate recognition of the second fact would have withheld Prof Horsley from expressing astonishment "a revelation to us" is his phrase—at finding the electrical variation in a nerve eight or ten times as great by direct electrical excitation as by discharge of a nerve centre. Du Bois-Reymond's analogous deflections obtained on strychninized frogs were  $1^{\circ}$  to  $4^{\circ}$  *versus*  $40^{\circ}$  by direct electrical excitation. A functional discharge *down* posterior roots, if proved to occur, is a new and surprising phenomenon, but its existence is not *at present* proved by the existence of an electrical discharge; electrical effects by electrical excitation are tainted evidence, electrical effects down the posterior roots by functional excitations above, although incidentally touched upon, were not exhaustively examined, and considering the recognized dangers of experimental fallacy, we may not admit as proved that nervous impulses are discharged down afferent channels. Prof Horsley infers unreservedly that functional discharge occurs *down* the posterior roots, and that centripetal impulses *up* the anterior roots are blocked at the cord. This he regards as striking evidence of the truth of the kinæsthetic doctrine (*i.e.*, that nerve action starts from the afferent or sensory side of the nerve centre, p. 170), but the connection between this presumed functional downflow in afferent channels and kinæsthesia is not made apparent; up-flow in afferent channels is matter of common knowledge; up-flow by efferent channels has (so far as we know) been contended for by no one since Lewes. But as regards these last points, they may be expected to receive fuller and more precise analysis in the promised volumes on the brain and on physiological psychology.

### ELECTROTECHNICAL TRAINING

*Electrical Engineering as a Profession and How to Enter It.* By A D Southam. (London Whittaker and Co, 1892)

THIS book consists of a collection of extracts from the notices of various firms regarding apprentices and articled pupils, and from the prospectuses of colleges which give an education in electrical engineering. It reminds us of the gorgeous but depressing volumes one has met so often in one's summer outing, containing particulars of hotels in Aden, hotels in Algiers, hotels in Andermatt, &c., each hotel possessing, at least so it is said in the gilt-edged page advertisement, every possible attraction—a magnificent view, a first-rate cuisine, electric light, ascenseur, and all the other dreariness of a bandboxy barrack.

NO. 1200, VOL. 46]

First we thought that the length of description which the author had given to a particular technical educational establishment was a measure of its goodness, but that idea we dismissed when we found that only three pages of description were given to that technical college in South Kensington, regarding which the author says "This institution deservedly stands at the head of all the technical institutions in this country." Next it occurred to us that the author might have acted on the "good wine needs no bush" principle, but that hypothesis had to follow the other, for we feel sure that the Walker Engineering Laboratory at Liverpool is not bad, and yet it requires fifteen pages of talking about. Then we wondered whether each professor had been asked to write as much as he liked, so that the length of the description of a particular set of laboratories was in proportion to the leisure of the writer, and lastly, we have been speculating whether the likeness to the "Hotels of the World" book might not be quite complete, and the length of the description was a measure of the length of the purse of the advertiser.

However, be the plan of the compilation what it may, the book contains a good deal of information, also some salutary advice with which we quite agree—"Undoubtedly the best training for a young man entering the electrical profession is to go through the course at one of the technical schools or colleges, and then when thoroughly grounded in the theory and having a general idea of the practice of his profession, to be articled for some months to a good firm of electrical engineers, where he will be able to acquaint himself with the practical part of his business as actually carried out on commercial principles," and again, "if he then goes to both a Technical College and is also articled, it is advisable that the former should precede the latter, for the reason that when he is placed in the workshop his previous technical training will enable him to appreciate and see the importance of much which he would otherwise have overlooked."

For the fathers who desire to place their sons directly in a works on leaving school, there is given a long list of engineering firms who are willing to receive £300 and the lad, some are willing to take only one hundred and twenty guineas a year, from year to year, or even as little as £100 a year—and the lad. In many cases a month's trial is allowed, but judging from the ignorance of elementary mathematics and science displayed by many articled pupils in works, we presume that either these subjects are not required, or a month is not a long enough time for this astonishing ignorance to be discovered. Naturally enough these firms do not bind themselves to provide work for these articled pupils when their term is finished, indeed we know of a firm with over 100 articled pupils which is applying elsewhere for an assistant.

When will the parental idea die out that a lad who is pitchforked into a works must turn out an engineer? No doubt many of our successful engineers never received any education in a technical college; so many of our battles were won by men armed only with bows and arrows, but that is no reason for confining the equipment of a modern regiment to these primitive weapons. Either the teaching given at a technical college materially helps the lad in his subsequent practice in the works, or it is a fraud and ought to be stamped out. If it affords real help

to the lad, then why, we ask, do not the firms insist on their pupils obtaining it before they enter the works?

Mere evening instruction for a lad who has been hammering, say, from 6 a.m. to 6 p.m. is well-nigh useless, and at the best ought to be regarded only as a makeshift for those who are compelled to spend the day earning their living. To place a lad at a technical college for two years, and then for two years at a works would cost, as far as fees and premium are concerned, about £250. To article him for three years at the works about £300. When will parents see that the cheaper course is far the better, and when will firms refuse to take an article pupil unless he has already acquired that theoretical knowledge which is necessary to enable him to benefit by a works training? The father who articles his son to an engineering firm immediately the lad leaves school and expects him to pick up his technical education at odd moments, may be more liberal in his money, but certainly is no more liberal in his ideas than the parents who sent their sons to receive their practical training at Dotheboys' Hall. "Now, then, where's the first boy?" "Please, sir, he's cleaning the back parlour window." "So he is, to be sure," rejoined Squeers. "We go upon the practical mode of teaching, Nickleby. C-l-e-a-n, clean, verb active, to make bright, to scour. W-i-n, win, d-e-r, der, winder, a casement. When a boy knows this out of a book he goes and does it." P.D.

#### HYGIENE AND PUBLIC HEALTH

*A Treatise on Hygiene and Public Health*. Edited by T. Stevenson, M.D., F.R.C.P. (Official Analyst to the Home Office), and Shirley Murphy (Medical Officer of Health of the Administrative County of London). Vol. I.

THIS is a treatise consisting of various contributions from different writers. In the selection of authors it has been wisely decided not to limit the choice to members of the medical profession, and the wisdom of this decision has been exemplified in the acquisition of two of the very best articles which the book contains, *viz.* that by P. Gordon Smith, F.R.I.B.A., and Keith D. Young, F.R.I.B.A., entitled "The Dwelling," and that by W. N. Shaw, F.R.S., headed "Warming and Ventilation."

There are at present several excellent small works upon hygiene and public health, but these of necessity treat of the subject in far too cursory a manner—indeed, they are designed more to meet the requirements of candidates for the Public Health Diplomas now granted by many examining Boards. This work is evidently intended as a book of reference, and there is no doubt that it will be of great value to those from whom a special knowledge of public health work is demanded. While, then, the last year or two have been remarkably fruitful in the production of works upon the subject here treated of, the volume before us will not be one jot the less appreciated on this account, for it meets a want which must long have been felt among those who desire a better and more inclusive knowledge of public health matters than was hitherto accessible in a collective form.

It is needless to insist that the work is all well done,

and that any shortcomings must, of necessity, be faults of omission rather than of commission, for the list of contributors includes those who occupy some of the foremost positions as authorities upon the subjects of which they treat. It is not an easy task—and one is conscious of running great risk of appearing arrogant—to single out those sections especially deserving of praise. If this is permissible in such a work, we should point to the two articles already mentioned as occupying a foremost place—indeed, the article upon "Warming and Ventilation" is a little too exhaustive and technical in its physical aspect, and deals too briefly and sparingly with the commoner provisions now used for both the purposes of warming and ventilation,—a shortcoming which has the effect of somewhat sacrificing the practical utility of the article to its bulk, when viewed from the health officer's standpoint. It would not be easy to speak in terms too high of the all-round excellence of the article upon "Disposal of Refuse," by Prof. W. H. Corfield, M.A., M.D., and Louis C. Parkes, M.D., D.P.H., and the work of compiling this section could not have been entrusted to more capable hands. "Water," by T. Stevenson, M.D., is a capital article, but one would like to have seen in it more about the methods of collecting water and distributing it, and of the risks which the water runs of pollution in and around dwellings.

In the preface we read that "it has been the desire of the editors that the several papers which these volumes contain should present a fair account of the knowledge, so far as obtainable, of the subjects of which they treat," and this is invariably achieved, for where the account is not an excellent one, it is always more than a "fair one."

The contribution upon "Air," by Prof. J. Lane Nottter, M.A., M.D., is too short, and does not nearly include all the material given in his edition of Edmund Parke's work, and the same fault may be found with the articles upon "Hospital Hygiene," by H. G. Howse, M.S., and "The Inspection of Meat," by E. W. Hope, M.D., D.Sc.

"Systematic Physical Education"—a subject which has been all too little studied in this country—is well and spiritedly treated of by F. Treves, F.R.C.S.

The articles upon "Baths," by H. Hale White, M.D., "Clothing," by G. V. Poore, M.D., "Food," by Sidney Martin, M.D., "Soil," by S. M. Copeman, M.A., M.D., D.P.H., "Meteorology," by G. F. Symons, F.R.S., "The Influence of Climate upon Health," by C. T. Williams, M.A., M.D., "Offensive and Noxious Businesses," by T. W. Hime, B.A., M.D., and "Slaughter Houses and their Administration," by E. W. Hope, M.D., D.Sc., are all good, though some of them might have been fuller. The article upon "The Influence of Climate upon Health" might with advantage have considered much more fully the reasons why the various climatic conditions influence the health of man in the way they do. The contribution upon "Meteorology," which is capitally illustrated, and one of the most useful in the book, might also have considered the physical causes which affect the readings of the various instruments, and dealt more fully with the principles upon which these are constructed. The article upon "Food" is excellent in some respects, but an attempt to convey to the reader, in an abstract form, the methods of food analysis fails—as

it always does when such a subject is treated of in brief space— to be of great assistance to the reader

The index is good, and the book is a valuable addition to Public Health literature.

### OUR BOOK SHELF

*Lehrbuch der Botanik nach dem gegenwärtigen Stand der Wissenschaft* Bearbeitet von Dr. A. B. Frank. Erster Band. Zellenlehre, Anatomie und Physiologie. 8vo 670 Seiten, mit 227 Abbildungen in Holzschnitt. (Leipzig: Wilhelm Engelmann, 1892.)

THIS is essentially a fifth edition of Sachs's renowned "*Lehrbuch der Botanik*," the fourth and last German edition of which appeared as long ago as 1874. An English edition, emended and augmented by the translator, Dr. S. H. Vines, was published in 1882. Now, ten years later, Dr. Frank has written a completely new work. As the author tells us in his preface, he was requested in 1890 to prepare a new edition of Sachs's book, but he has adopted the wiser course of making himself responsible for the whole. Nevertheless, free use has been made of Sachs's excellent illustrations, upwards of ninety out of the two hundred and twenty-seven having been taken from that source, "because the author could not replace them by better ones." About sixty are borrowed from other authors, and about seventy of them are original, or at least Dr. Frank's own, for some of them have appeared elsewhere. A number of them are reduced from Frank and Tschirch's "*Wandtafeln*." Certainly the book is admirably illustrated. In the limitation and arrangement of the material the author has followed Sachs in a general way, though he has separated the physiology and anatomy from morphology and classification. The two latter branches are to be dealt with in a second volume, promised early next year. So far as the present volume is concerned, we can strongly recommend it to the student familiar with the German language. It is written in a clear, succinct style, and, so far as we have been able to test it, it is well up to date. Dr. Frank is well known as a writer and teacher of botany, and especially for his researches and experiments relating to the nutrition of plants. The sources of the nitrogen of plants and symbiosis are two subjects to which the author has devoted much attention, and they are discussed in some detail from his own standpoint. We are glad to see that copious and complete references are given to the books and articles of the principal writers on the various subjects, whose views are discussed or adopted. Unfortunately there is no index, and it is not easy to find one's way through the table of contents. True, a "carefully prepared" index is promised with the second volume, but a separate one to each volume would be far more convenient and time-saving. It is not as though the second volume was a continuation of the first, and it is to be hoped that the author and publisher will even yet see their way to provide this facility for using the work.

*Arithmetical Chemistry*. Part II. Book B. By C. J. Woodward, B.Sc. (London: Simpkin, Marshall, Hamilton, Kent, and Co. Birmingham: Cornish Bros., 1892.)

THE student will find in the present edition of this work what is practically a new book, as the author has enlarged and entirely rewritten the original publication. The opening lessons treat of analyses, the formulæ of minerals, Dalton's law of partial pressures, gas analysis, &c., and are on the whole satisfactory. The introductory portions of the lessons, which embody the principles involved in the exercises, and contain typical examples fully worked out, are clear, as a rule, and the exercises themselves are both suggestive and useful. The same may be said of

the concluding part of the book, wherein are briefly discussed atomic weight determinations, and the various means of controlling atomic weights, calorific power and intensity, heats of formation, dissociation, and gaseous phenomena, comprising the kinetic theory, diffusion, and absorption by water.

The intermediate lessons on molecular weights are, however, not up to the standard of the others. It is not made plain when discussing Avogadro's law that a vapour density observation, when possible, is the decisive mode of fixing the molecular weight of a compound. The vague description of the apparatus used in measuring osmotic pressure can only confuse the reader, and loose statements such as "*solutions behave as gases*," p. 51, must have the same effect. The relationships established in connection with the vapour pressures of solutions only hold if the dissolved substance is practically non-volatile, this point is omitted, and the definition given of equimolecular solutions is not the one in common use. Indeed, the entire treatment of the properties of solutions as applied to molecular weight observations, although it may perhaps enable the student to solve problems, is much too fragmentary and loosely put together to give him an adequate idea of what is known on the subject. It may also be pointed out as somewhat late in the day to give a few of Kopp's conclusions as an account of specific volume.

Among minor corrections it may be noted that on p. 6, in the first erratum, solvent should be solution, vapour-tension might often be replaced by vapour-pressure, xylol should be xylene, and amyl benzoat should be amyl benzoate, on p. 48. "*Ostwald's Solutions*" might be included in the list of English works to which the student is referred.

The book contains an index, a list of answers, and a collection of the questions in arithmetical chemistry set at the Honours examinations of the Science and Art Department, and at the B.Sc. examinations of London University. A portion of the author's A.B.C. Five figure logarithms is presented with this edition. J. W. R.

*Lessons in Heat and Light*. By D. E. Jones, B.Sc. (London: Macmillan and Co., 1892.)

THE success of a previous work on "*Heat, Light, and Sound*," has led Prof. Jones to extend the two former parts, and publish them separately for the use of schools and junior classes in colleges. As an introduction to the study of experimental physics, the book cannot fail to be of great value. The principles of the subjects are very clearly stated, and the experiments from which they have been deduced are fully described. Most of the experiments may be easily performed by students, the instructions being sufficiently clear to guarantee success. Numerous arithmetical examples, partly selected from the author's "*Examples in Physics*," are added at the ends of the various chapters. The physiographic bearings of the subject of heat have been brought well to the front, thus the origin of the Gulf Stream, trade winds, and the formation of rain and snow are explained. Many of the diagrams have been carefully drawn to scale, in order to give the student an idea of the dimensions of the apparatus which may be conveniently employed in performing the experiments.

*Elements of Magnetism and Electricity*. By John Angell, F.C.S., F.I.C. (London: Collins, Sons, and Co., 1892.)

THIS is a new edition of one of the best known textbooks for use in connection with the classes under the control of the Science and Art Department. The book calls for no special remark, but the fact that a hundred thousand copies have already been disposed of seems to demonstrate its usefulness. Experiments and illustrations are its special features.

## LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

## Further Notes on a recent Volcanic Island in the Pacific

THE volcanic island—Falcon Island—in the Tonga group in the Pacific, of the recent appearance of which an account is given in NATURE, Vol. xli, p. 276, has recently been passed by a French vessel of war, the *Duchaffault*, which reports that the island is not now more than 25 feet high.

In October, 1889, when examined by Commander Oldham, it was 153 feet high, and a little over a mile long. Nearly entirely composed of ashes, it was rapidly washing away, and by the account above, it would seem that more than one half the island must now have disappeared. W. J. I. WHARION.

## Earth fractures and Mars "Canals"

ON seeing the figure of the so-called "canals" of Mars, published in NATURE of a few weeks back, I was at once reminded of the pattern assumed by the cracks of glass broken by torsion, as in Daubrée's well-known geological experiment.

I enclose a photograph of part of a large slab of glass broken in this way in a class experiment of my own, and although other slabs, which have unfortunately not been preserved, exhibited, if I remember rightly, still more Martial-looking networks, I think that the general resemblance is obvious enough in this case.

It may perhaps be well to explain to non-geological readers of NATURE that Daubrée's glass-breaking<sup>1</sup> is regarded by many as reproducing in miniature the kind of fractures which are found to occur in those portions of the earth's crust with which we are acquainted, and that by torsion only has it proved possible to imitate the peculiar pattern assumed by such fractures, whether

they be joints or dislocations. It is further held by many that such lines of fracture in such patterns are a necessary result of the shrinking of the outer coat of a planet in course of cooling.

Mere fractures, such as we meet with in our own planet, could, of course, not be seen from any considerable distance, and if the circumstances of denudation were the same in Mars as with us, the "canals" could certainly not be the representatives of our usually hidden and featureless earth-cracks. There seems, however, to exist, in the extraordinarily rapid melting of gigantic ice-fields described by Prof. Norman Lockyer, some evidence of denuding power in Mars on a scale enormously larger than is the case with us. Earth-fractures—and for the matter of that Mars fractures too—must many of them be lines of weakness along which denudation acts more freely than elsewhere, and if this denudation be phenomenal and cataclysmic, as appears to be likely in Mars, wide valleys or channels capable of being distinguished at great distances would soon be scoured out along them.

<sup>1</sup> Not "ice-breaking" as a mistranslation of the word "glace" has caused it to be described in some English text-books.

I would wish especially to draw attention to the three following points observable in the photograph, viz., the two marked directions in which the crack lines run, one set crossing the others often at, or very nearly at, right angles, their occasional doubling and rough parallelism for some distance, and their frequent sudden stoppage—three of the features most noticeable in the Mars lines. G. A. LEHOUR.

## A Wave of Wasp-Life

MR. HUDSON's charming work on "The Naturalist in La Plata" reminds me of a very interesting wave of wasp life which appeared in Wisconsin in the summer of 1886. We were living at the time in our summer house at Pine Lake, and were making observations on the habits of the different animals in the neighbourhood.

In the latter part of July we suddenly found ourselves surrounded by large numbers of yellow jackets and hornets everywhere through the woods and fields a veritable plague of wasps seemed to have descended upon the earth. During all the month of August we heard the same report from summer residents within a radius of twelve or fifteen miles of Pine Lake. In our immediate neighbourhood we knew of forty-seven nests. Allowing 1500 wasps to a nest—a very low estimate for that season of the year—this gave us over 70,000 wasps. Plates of meat and bones that were set outside for the cats were immediately covered with them, and in spite of screens in doors and windows they even entered the house, alighting on the food at the dinner-table, or darting about and catching flies.

The cause of this sudden increase in the number of wasps was evidently a general one, since it acted in the same way upon three species—*Vespa vidua*, *V. maculata* and *V. germanica*. An examination of the Signal Service statistics does not show anything unusual in the preceding winter and spring, but either the weather must have been especially favourable, lessening the ordinary death rate of the queens, or there must have been a marked decrease in the parasites or other enemies which ordinarily keep these species in check.

The duration of the favourable conditions proved brief enough. It is probable that every one of our forty-seven nests furnished, at the very lowest estimate, one hundred developed and fertilized queens to start forty-seven hundred new nests in the following year, yet the increase in the checks to the too great ascendancy of these species more than counterbalanced the abnormal increase. The winter of 1886-87 was not especially severe, but in the following summer the most careful search on our part, and on the part of others, whose efforts were stimulated by the offer of rewards, only gave us four nests in our neighbourhood, and on all sides we were met by the inquiry "What has become of the wasps?"

## Note on the Occurrence of a Freshwater Nemertine in England.

A FEW days after reading M. de Guerne's "History of Freshwater Nemertean," published in the August number of the *Annales*, I happened upon a specimen of the group amongst the roots of some water plants, which I collected in the river Cherwell, close to Oxford. I was, at the time, searching for the cocoons of a new Rhinodrilid worm, of which a description will shortly appear. The gathered roots, with the cocoons, were placed in a bottle of water, in order that the worms might hatch out. On examining the bottle two days later, namely, on September 5, I noticed a small bright orange animal, about half an inch long when extended, creeping amongst the cocoons. Further observation with the microscope showed that it was a species of *Tetratemma*. Unfortunately the animal was crushed before I had done more than sketch the general appearance and make some few observations, and I have not yet succeeded in finding more specimens, so that I am unable to state how far it agrees with or differs from the previously known freshwater forms enumerated by M. de Guerne, most of which are included by Silliman and later authors under the title *Tetratemma aquarum dulcium*.

In one or two points, however, my sketches show certain differences from those of Silliman—

- (a) The colour (orange) is due to pigment in the skin, and not to the red colour of the nervous system. I may mention that Duges' species, "*Prostoma clepsinoides*," was yellow ochre, and "*Pr. umbracordeum*" was yellow marbled with red; whilst Leidy's "*Emea rubra*" was yellowish flesh-coloured (probably due to the hæmoglobin in the nervous system)
- (b) The anterior pair of eye-spots is further from the prostomium than in Silliman's drawing, I found no third pair of eye spots, which, however, it is stated, is absent in the young
- (c) The ciliated pits are further forward, being midway between the brain and the anterior end of the body
- (d) The proboscis and its retractor muscle are much more undulating, when withdrawn into the body, than Silliman shows

The proboscoidal spine, with its groups of accessory spines, agrees very closely with the figures given by Silliman

I can say nothing about the generative organs. For the present, then, I must leave undecided the specific name of this British *Tetrastemma* W. BAXIAND BENHAM

### Protective Mimicry

MR BATESON'S letter on "Aggressive Mimicry" (NATURE, October 20) recalls to my mind a curious case of protective mimicry which came under my notice last August on Dartmoor. Large patches of the heath had been burnt, a common practice on the moorlands to ensure a fresh young growth for the sheep. The whole ground was alive with a common species of orthoptera (*Locustina*), the small green grasshopper with short antennæ. They leapt aside at every step in the short grass and scrubby heath, upon the burnt patches they were equally numerous, but with this difference—all, without exception, were coal black on abdomen, thorax, and head, whilst the wings were of an ashen hue. So much did the colour adaptation resemble the blackened turf and heath they hopped amongst it was almost impossible to follow them with the eye, we made many amusing attempts, but were nearly always defeated. I measured one of these burnt patches, and found it to be from thirty to forty yards square. A yard or two from this, on the untouched herbage all the *Locustina* were bright green. I found one specimen on the borderland in a transition state, not dull all over as I had expected, but in spots and patches of bright green and black. One enemy at least of these insects abounded on the moor, namely, the common lizard (*Zootica vivipara*), for I have observed there is no food lizards will eat more greedily than grasshoppers. I have seen some that I have in captivity swallow twenty or thirty in two or three minutes, even after their usual meal of worms. They always became greatly excited, if one may apply so warm an expression to such cold blooded animals, and rushed about the case when a collection of live grasshoppers were thrown to them. Certainly I was much struck by the rapid action of the power possessed by these *Locustina* on Dartmoor of assimilation to environment, and did not doubt but that this colour adaptation was for the purpose of protection, the eye producing by reflex action the change in the pigment cells. ROSE HAIG THOMAS

### STELLAR PARALLAX<sup>1</sup>

THE Delegates of the University Press have recently published the results of Prof Pritchard's systematic investigations into the parallax of those stars of the second magnitude whose North declination permits the inquiry to be made with facility and advantage in these latitudes. Our first feeling on glancing over the contents of this brochure must be one of hearty congratulation to the distinguished professor that he has been permitted to see the full outcome of a protracted inquiry, conducted at a period in his life when a less energetic astronomer would have felt himself justified in withdrawing from active participation in scientific research.

<sup>1</sup> "Researches in Stellar Parallax by the aid of Photography" By Charles Pritchard, D.D., F.R.S., Savilian Professor of Astronomy in Oxford

Prof Pritchard might well have been content to rest on the laurels he had won, and to have staked his reputation upon that career of acknowledged utility which has marked his direction of the Oxford University Observatory.

Immediately on the completion of the photometrical examination of Argelander's Uranometria, and with a zeal that admitted of no delay, Professor Pritchard busied himself with this inquiry into the parallax of stars of the second magnitude. But if the inquiry was undertaken with eagerness, and pursued with ardour and resolution, it was not characterized by hurry, or its success imperilled by incompleteness. Confident himself that photographic methods possessed the requisite accuracy to make the research successful and trustworthy, the Savilian Professor set to work to establish the reliable character of measurements made on sensitized films, and not till that confidence was demonstrated did he embark upon the larger work now under notice. These preliminary inquiries have been published in a series of papers in the proceedings of the Royal and Royal Astronomical Societies, and the confidence gradually acquired by enlarged experience induced him to proceed with the determination of the parallax of 61 Cygni, the results of which are published in detail in the third fasciculus of the Annals of the University Observatory. In this case he selected four stars in the immediate neighbourhood of the principal star, and sought the difference of parallax between each of the components and of the four stars of comparison. This long research may be regarded by some as a work of supererogation, inasmuch as the labours of Bessel and that of many later astronomers have satisfactorily settled the parallax of this star within very approximate limits. But if we properly understand the motives of Prof Pritchard, his intention was not so much to seek anew the parallax of that system, as to discover with what degree of accuracy the method of photography, hitherto unapplied in this direction, represented the work of others made directly in the field of the telescope. Nor was this his only view. By selecting four stars in the immediate neighbourhood of 61 Cygni and seeking the difference of parallax between these stars of comparison and each of the components of the system, he instituted a very severe inquiry as to the trustworthiness of that method, which he had imagined as capable of dealing with the delicate question of stellar parallax. The severity of the test consists in deducing the same value of the parallax (eight in all) from each set of measures, and as a matter of fact the accordance, *inter se* between these several determinations is as close as could have been anticipated, and likewise in satisfactory unison with the work of other astronomers.

The completeness of this inquiry and the publication of it in detail have had two happy results. In the first place, Prof Pritchard has, in the present instance, been able to confine the printing within very narrow limits, so narrow, indeed, as possibly not to have done himself justice. The details of his process, the mutual agreement of his measures, and his method of discussion having all been fully set out in his previous work, he has not felt himself obliged to enter into these minute particulars, but has contented himself with presenting the results. This method of arrangement, no doubt suggested in the first place by economical motives, has afforded opportunity for adding a very interesting history of the processes and results that have hitherto been followed with more or less success by others, and also the exhibition in a concise form of the different values of the more trustworthy determinations, derived by previous observers. The second advantage, immediately arising from the earlier investigations, is, that an examination of those results has shown that no increase of accuracy (commensurate with the increased labour at

least) was obtained by continuing the observations of the stars throughout the whole of the year, that is, to secure observations in all positions of the parallactic ellipse. If the measures were confined to those epochs when the parallactic displacements were greatest, and a sufficient number of observations secured at those critical times, a determination of parallax could be relied upon to within about one thirtieth of a second of arc. This is approximately the limit of accuracy that Professor Pritchard hoped to reach, and in this selection he appears to have been guided by the conviction, that in the present condition of cosmical inquiries, to which stellar parallax bears the closest relation, it is of more importance to know within very narrow limits the parallaxes of many stars than seek with the utmost accuracy the parallax of a very few. And in this respect there can be no doubt but that Prof. Pritchard's judgment is correct. The former is the view of a philosopher, the latter that of a conscientious and painstaking observer. Guided by the broader view, the result of his work has been to enrich the data at the command of students of cosmical science by assigning the approximate distance to some thirty stars, a number which bears no inconsiderable proportion to the total number of separate determinations made by all other astronomers combined.

Prof. Pritchard's view of the history of stellar parallax is that of a scientific struggle, a continual and severe wrestle on the part of the astronomer with the inevitable inaccuracy of observation and imperfect instruments, in which sometimes one opponent, sometimes the other, has the mastery. He passes in his historic survey rapidly over those days when from various obvious causes the detection of stellar parallax was scarcely possible, moved however to admiration by, and induced to linger over, the success that attended the early observations of Molyneux in the case of  $\gamma$  Draconis when discussed, a century later, by Auwers, a success that later observers have struggled to repeat ineffectually. He brings before us, but touches with a light and kindly hand, the dispute that embittered the lies of Brinkley and of Pond, but it is not difficult in reading a little between the lines to see with whom his sympathies rest. Later on in the history of the research, Henderson meets with his deserts, as a clear-sighted astronomer of distinguished ability, cautious and persevering, and one who in the struggle after accuracy obtained an undoubted measure of success. This historical introduction will we think be read with pleasure by many whom it may have no particular interest in this special subject of inquiry. The comments of one who has encountered and overcome many similar difficulties, and has kindly sympathy with all who have travelled along the same path, cannot but be of interest and of value, and we could have wished that this portion of the book had been considerably extended. How many astronomers are now acquainted, with any degree of adequacy, with the serious difficulties that attended the early application of the heliometer in this department of research, and with the dispute that raged long and dubiously around the names of Wichmann and of Schlüter? All are willing to admit that in the hands of many competent observers—it would be invidious to mention any without naming all—the heliometer is doing splendid work, but the difficulties with which the early masters had to cope are now all but forgotten, and it is certainly wise to treasure a sympathetic remembrance for the earlier exponents of the improved and successful methods now in vogue.

The last portion of Prof. Pritchard's history is occupied with the bearing of stellar parallax on the problem of the construction of the stellar universe. He seems to have had before his mind two questions, which, long hovering in an unexpressed form, were first formally enunciated by Dr. Gill. The first question is, What are the average parallaxes of stars of the first,

second, third, and fourth magnitude respectively compared with those of fainter magnitude? To this question the Savilian Professor replies very cautiously. The researches of Dr. Elkin on stars of the first magnitude point to an average parallax of  $0''.089$  for stars of that class, and just as certainly Prof. Pritchard's researches point to an average parallax of  $0''.056$  for stars of the second magnitude. But he pertinently asks what can be understood by an average of distances (as indicated by parallaxes) in cases where the separate elements vary from actual zero to half a second, and where moreover many of the brighter members are the furthest removed from us? Notwithstanding these exceptional cases, which challenge attention, the fact remains and it is apparently the only conclusion which can be drawn with any certainty, that the stars of the first magnitude are on the whole nearer to us than those of the second, and that these again are as a whole nearer to us than the faint stars with which they have been compared. With conclusions of this sort it would seem that astronomers will have to content themselves for some time to come.

The second question which Dr. Gill suggested or formulated was—What connection does there exist between the parallax of a star and the amount and direction of its proper motion?—or can it be proved that there is no such connection or relation? The answer given to this second query is even less satisfactory than to the former. Prof. Pritchard contents himself by exhibiting in a tabular form the parallax and the proper motion of all stars that have been successfully handled, and the only conclusion drawn or warranted, is a suggestion that there is at least quite as close a connection between the apparent proper motion of a star and its distance from us, as there is between its distance and its magnitude.

If we examine or attempt to trace any connection between the mass, the brilliancy and the distance of a star, we are baffled by the same kind of uncertainty, arising in some measure from the paucity of instances in which it is possible to make the inquiry, and we are reluctantly forced to admit that such investigations are premature. At least that would be the conclusion of an ordinary mind, but here it is that Prof. Pritchard sees his opportunity for future efforts and renewed vigour. With an energy that must be the admiration of his friends, he selects for further investigation two subjects, either of which might fully occupy the time and the hands of a younger man. He proposes in the first place to determine the parallaxes of several stars of the Pleiades, a few of the brighter as well as a few of the fainter, with the view of discovering whether the faint and the bright are indiscriminately mixed at that distance. The second subject of his proposed inquiry is not less interesting. It consists in the investigation of the distances of some of the binary systems from our sun, and from a more complete knowledge of the masses, the mutual distances, and the parallaxes of these systems, Prof. Pritchard thinks it not unlikely that many interesting and possibly unexpected associations may reasonably be anticipated, thereby affording us some further insight into the constitution and the mechanism of the Stellar Universe. We can only hope that Prof. Pritchard's health and strength may be spared to witness the completion of this programme, but in that case we are assured he would immediately sketch out for himself some new field of inquiry, and court even longer and more protracted labour.

#### CONTRIBUTIONS TO THE STUDY OF DISINFECTION<sup>1</sup>

PROFESSOR J. MASCHKE, whose name is already familiar to us through his investigations on water bacteria, has brought together in pamphlet-form a large

<sup>1</sup> "Beiträge zur Theorie und Praxis der Desinfection, von Prof. J. Maschke." Im Selbstverlage des Verfassers, Leinert.

number of experiments on the relative value of various disinfectants and disinfectant processes. Since the introduction of Koch's methods, the study of the subject of disinfection has been immensely assisted, and it is now possible to take a more accurate measure of the extent to which micro-organisms are affected by different treatment, whether chemical or mechanical. The stimulus which it has thus received has not unnaturally drawn a large number of workers into this particular field of inquiry, and the literature is already very unwieldy.

One of the principal difficulties which surround the study of micro-organisms is their individuality, their apparent idiosyncrasies, and this is not confined to closely allied varieties, but is found amongst members of one and the same species. Thus, the previous history of a micro-organism, the nature of the culture material used, the temperature at which the cultivation has been kept, the age of the growth, &c., are all points which have to be taken into consideration as likely to influence the behaviour of the particular specimen under observation. This sensitiveness of bacteria may possibly to some extent account for the discrepant results which have been obtained by different investigators, although working in similar directions, which has rendered the accurate appreciation of the value of these results a by no means easy task. Again, what succeeds in a laboratory is not necessarily equally successful when carried out on a large scale, and it is this difficulty which has so frequently led to such disappointing results in actual practice.

Prof. Maschek has endeavoured by a series of most arduous and painstaking experiments to throw a little more light on some of the problems of disinfection, and in gathering up his work has wisely abstained from attempting an exhaustive survey of the general literature, restricting himself to a brief introduction and particular reference to those investigations with which he has been more closely concerned. In the majority of the experiments the author employed Koch's well-known method of sterilized silk threads, each of which was subsequently impregnated with pure cultivations of a number of different pathogenic micro-organisms. These were distributed in various parts of a room about 19-ft long, 13-ft wide, and 15½-ft high, on the ceiling, walls, corners, floor, &c., whilst in some cases they were wrapped up in different materials, such as filter-paper, muslin, linen, in order to imitate as nearly as possible the actual conditions under which the organisms might be supposed to be present in an infected room. In each case, after the application of the disinfectants under observation, these silk threads were submitted to plate-cultivation, and in some instances their pathogenic properties were also tested by inoculation into animals.

The first elaborate series of experiments was made with the vapour of corrosive sublimate, which some authorities have recommended as an effective germicidal agent, but quite apart from the difficulty of getting rid of the poisonous crystals of corrosive sublimate which remained attached to various parts of the room, Prof. Maschek was not able to obtain satisfactory results, although every precaution was taken to ensure success. In this respect his experiments differ from those of König, who confidently recommended its use for disinfection purposes. The effect of chlorine gas was next tested and applied both in the dry and damp state. The results were, however, far from encouraging, for even when employed in the damp state the spores were not destroyed. In connection with these experiments a very instructive instance is given of the signal failure which accompanied the use of chlorine in the Alexander Hospital in St. Petersburg, which was designed for receiving different infectious illnesses. Suspicion as to its efficacy was first aroused after its use in the disinfection of a ward in which diphtheria patients had been treated.

This ward was afterwards used for scarlet fever cases, and subsequently complications with diphtheria made their appearance, in consequence of which the ward was closed and disinfected with chlorine. (A ward of 900 cubic metres capacity being subjected to the chlorine gas evolved in treating 50 kilos of chloride of lime with 65 kilos of hydrochloric acid.) After the disinfection was completed, the ward was thoroughly cleansed and ventilated, and allowed to remain empty for seven months. On its being re-opened for the reception of measles cases complications with diphtheria again arose, although the patients when taken into the ward were wholly free from diphtheria. The measles patients were therefore removed, and the ward was again disinfected with chlorine, only this time a much larger quantity was employed (135 kilos of chloride of lime with 148.5 kilos of hydrochloric acid) after which it stood empty for another seven months. Later on cases of smallpox were received into this ward, but diphtheria again appeared, the physician, two nurses, and an attendant being amongst those attacked, whilst complications with diphtheria again occurred amongst the patients. In consequence of this the unfortunate ward was once more closed and thoroughly disinfected with chlorine, and was reopened for typhoid fever patients, but all children's cases were rigorously excluded, in consequence of their particular susceptibility to diphtheria. After the adoption of this special precaution no further attacks of diphtheria were met with. It might, however, be urged that as regards the infection of patients suffering from measles with diphtheria, the disease was possibly introduced from outside, and did not necessarily arise in the ward itself, were it not for the fact that there were three other wards in the hospital in which cases of measles were being treated at the same time, and no single attack of diphtheria occurred. Krupin, who is the authority for these facts, confirming the valuelessness of chlorine for disinfecting purposes, found that the spores of anthrax were not destroyed in a hospital ward after being exposed to the action of this gas for more than 40 hours.

A large number of experiments were made with a view to determining the number of micro-organisms present on the walls of a room. For this purpose a small sterilized bit of sponge cut in the shape of a cube (of about half-inch side) was used to rub down a measured portion (about 4 square inches) of the wall. The sponge was afterwards placed in a tube containing sterile melted gelatine and rotated gently, so as to disengage all the organisms on its surface. The gelatine was then allowed to congeal on the sides of the tube, and after suitable incubation the colonies made their appearance, and were estimated in due course. It was found that the numbers present on the walls and ceiling respectively varied considerably. Near the floor the number was much greater than on the middle of the wall, whilst here again they were more abundant than on the ceiling. For example, on one of the walls, at a distance of rather more than an inch from the ground, as many as 2,871 microbes were found, whilst on the ceiling over a similar area only 85 were discovered. It was also noticed that those portions of the wall or ceiling which were exposed to currents of air from either the window or door exhibited generally a smaller number of bacteria than did places which were shielded from such draughts. Prof. Maschek further found that one rubbing was wholly insufficient to remove all the organisms from a given surface, and it was only after the process had been repeated five times that all bacterial life could be banished with certainty. Although the figures thus obtained are of interest by way of comparison, yet it is difficult to believe that they represent the actual numbers present. The accuracy of this method, originally devised by Esmarch, rests on the assumption that on placing the sponge in the tube of melted gelatine and rotating it gently (for if this were done

violently the gelatine would froth, and the surface become covered with small bubbles, which would greatly interfere later with the counting of the colonies) all the organisms attached to the surface of the sponge would be removed. Now the sponge being left in the tube must necessarily obscure part of the gelatine surface, moreover, the interstices becoming soaked with gelatine, colonies would certainly develop within the sponge itself and escape detection, whilst it is quite inconceivable that gentle rotation would suffice to detach even all those organisms which are adherent even to the surface of the sponge.

Wall surfaces deprived of micro-organisms in the manner described above were subsequently sprayed with distilled water infected with different pathogenic bacteria, and after sufficient time had elapsed for these surfaces to dry, the effect of various disinfectants was tried. Numerous investigations are also recorded of the use of creolin, carbolic acid, and mixtures of the latter with solutions of corrosive sublimate. The effect of exposure to high temperatures, in apparatus specially constructed for the purpose, has also been tried, whilst the disinfection of sewage matters with lime is also carefully considered, and a large number of experiments recorded with the typhoid and cholera organisms.

The following interesting account is given as an illustration of the success which can be achieved in disinfection on a large scale. An epidemic of diphtheria broke out in a small village in Germany and proved particularly fatal amongst the children, indeed so alarming was its progress, that the Burgomaster was led to suggest the disinfection of the whole village. A public meeting was held and the inhabitants were instructed as to the nature of the epidemic, and the possibility of checking it by the combined action of every household. Public funds were devoted to the purchase and distribution of the requisite disinfectants, and during three days the whole place is described as smelling of carbolic, whilst in all directions windows and doors were to be seen wide open, a very unusual sight in the country, and more especially in the month of February when this occurred. The work of disinfection was carried on most systematically, every article which could not be either washed or baked was treated with a 5 per cent solution of carbolic acid. In short, no efforts were spared to thoroughly disinfect everything, and the result was that although the epidemic before the commencement of this disinfecting crusade was steadily gaining ground, it suddenly stopped. This must be considered as a tribute to the sagacity and energy of the inhabitants, for, as Prof Maschek points out, experience teaches us to expect a gradual decline, due to the possible weakening of the virus, so that towards the end of an epidemic the number of bad cases is lessened and recoveries are more frequent.

In conclusion the words of M Duclaux may be appropriately quoted. "Les études sur les antiseptiques n'ont gagné que de s'encombrer de résultats qui se contredisent les uns les autres, et entre lesquels on ne peut faire un choix, précisément parcequ'ils ont été souvent obtenus en dehors des conditions d'une étude précise. Il faut donc abandonner cette méthode, scruter avec de plus en plus de soin la phénomène, faire de la science, en un mot." This "*faire de la science*" is precisely the spirit in which Prof Maschek has carried out his experiments, the immense care with which they have been conducted, the ungrudging labour bestowed upon them should render his results a most valuable contribution to the subject of disinfection. It is only to be regretted that they are not published in a form in which they would be more likely to become known and appreciated.

GRACE C FRANKLAND

NO. 1200, VOL. 46]

# AN ETHNOGRAPHICAL SURVEY OF THE UNITED KINGDOM

A CIRCULAR letter, which we have been asked to print, has just been issued on behalf of the Committee appointed by the British Association to organize an ethnographical survey of the United Kingdom. The Committee consists of Francis Galton, F.R.S., J. G. Garson, M.D. and J. W. Brabrook, F.S.A., representing the Anthropological Institute, Edward Clodd, G.L. Gomme, F.S.A., and Joseph Jacobs, M.A. representing the Folk-lore Society, H. S. Milman, Director S.A., George Payne, F.S.A., and General Pitt Rivers, F.R.S., representing the Society of Antiquaries of London, Joseph Anderson, LL.D., Secretary of the Society of Antiquaries of Scotland, and A. C. Haddon, M.A., Professor of Zoology at the Royal College of Science of Dublin. The following is the circular letter—

SIR,—The above-named Committee, in pursuance of the object for which they have been delegated by the Society of Antiquaries of London, the Folk-lore Society, and the Anthropological Institute, and appointed by the British Association, propose to record for certain typical villages and the neighbouring districts—

- (1) Physical Types of the Inhabitants
- (2) Current Traditions and Beliefs
- (3) Peculiarities of Dialect
- (4) Monuments and other Remains of Ancient Culture, and
- (5) Historical Evidence as to Continuity of Race

As a first step, the Committee desire to form a list of such villages in the United Kingdom as appear especially to deserve ethnographic study, out of which a selection might afterwards be made for the Survey. The villages suitable for entry on the list are such as contain not less than a hundred adults, the large majority of whose forefathers have lived there so far back as can be traced, and of whom the desired physical measurements, with photographs, might be obtained.

It is believed by the Committee that such villages may exist in the districts with which you are acquainted, and, as you are eminently capable of affording help in this preliminary search, we have to request that you will do so by kindly furnishing the names of any that may occur to you, with a brief account of their several characteristics, mentioning at the same time the addresses of such of their residents as would be likely to support the Committee in pursuing their inquiry.

They would also be glad to be favoured with the names of any persons known to you in other districts to whom this circular letter might with propriety be addressed.

We are, Sir,

Yours faithfully,

FRANCIS GALTON, *Chairman*  
F. W. BRABROOK, *Secretary*

All communications should be addressed to "The Secretary of the Ethnographic Survey, British Association, Burlington House, London, W."

## NOTES

THE Board of Trinity College, Dublin, on October 22 elected Dr Arthur A. Rambaut, M.A., Royal Astronomer of Ireland, on the foundation of Dr Francis Andrews. The election was made under the provisions of Letter Patent 32 George III., dated in 1792. The new Professor of Astronomy in the University of Dublin, graduated in 1881 as a Senior Moderator and Gold Medallist in Mathematics, since which period he has acted until now as Assistant at the Observatory at Dunsink.

He is the author of several astronomical papers published in the Transactions of the Royal Irish Academy and of the Royal Dublin Society

It is proposed that a portrait medal of M. Hermite, the eminent mathematician, shall be struck in commemoration of his approaching seventieth birthday. The circular asking for subscriptions is signed by a number of well known mathematicians

THE following nominations have been made for the Council of the London Mathematical Society for the session 1892-3. The ballot will be taken on November 10. For President, A. B. Kempe, F.R.S., Vice Presidents, A. B. Basset, F.R.S., E. B. Elliott, F.R.S., Prof. Greenhill, F.R.S., Treasurer, Dr. J. Larmor, Hon. Secs., Messrs. M. Jenkins and R. Tucker, other members, Mr. H. F. Baker, Dr. Forsyth, F.R.S., Dr. Glaisher, F.R.S., Mr. J. Hammond, Prof. M. J. M. Hill, Dr. Hobson, Mr. A. E. H. Love, Major Macmahon, F.R.S., and Mr. J. J. Walker, F.R.S. After the election of the Council Prof. Greenhill will read his Presidential Address

IN consequence of the alterations in the rooms of the Chemical Society, the first ordinary meeting of the Society will be held on Thursday, November 17, at 8 p.m.

THE late Dr. C. A. Dohrn left his magnificent entomological collections, with the library connected with them, in trust to his son, Dr. H. Dohrn, who was directed to use them as the nucleus for the formation of a natural history museum in Stettin. Dr. H. Dohrn has now not only carried out his father's wishes, but has presented to his native town his own conchological collections and library

THE Geologists' Association will hold a conversazione on Friday, November 4, in the Library of University College, Gower Street. Among the exhibits will be a series of photographs of the recent eruption of Mount Fina. These will be shown by Mr. F. W. Rudler

MR. M. C. POTTER has been appointed to the Chair of Botany at the College of Science, Newcastle-on-Tyne

THE annual meeting and conversazione of the Postal Microscopical Society took place at the Holborn Restaurant on the 20th inst. There was a good attendance, and many microscopical specimens were displayed. An address on polarized light was delivered by Mr. G. H. Bryan, the president

THE following lectures will be given at the Royal Victoria Hall on Tuesday evenings during the coming month:—Nov. 1, Prof. A. H. Green, "Coal, what it is and how it was made," Nov. 8, W. D. Halliburton, M.D., F.R.S., "The history of some famous epidemics," Nov. 15, Hermann H. Hoffert, D.Sc., "Electric sparks and lightning flashes," Nov. 22, Prof. Hall Griffin, "Among the hills of Asolo: an illustrated account of the poem 'Pippa Passes'."

NATURALISTS who visit the Zoological Society's Gardens should not fail to go to the Insect House and see the Pratincole, which has lately been received, and is kept in a cage in this building. So far as we know, it is the first example of this curious form of plover that has ever been seen in captivity. The specimen in question does not, however, belong to the Pratincole of the south of Europe (*Glaucola torquata*), which has sometimes occurred in this country, but to an allied African species—the Madagascar Pratincole (*Glaucola ocularis*). The bird was obtained near Mombasa, in Eastern Africa, and presented to the society by Mr. R. MacAllister. It was carefully brought home, along with many other interesting specimens, from Zanzibar and the adjoining mainland by Mr. Frank Finn, F.Z.S., on his return from his recent expedition to that country

A CORRESPONDENT from Tangier writes that during the recent mission to Fez of Sir Euan Smith, Mr. Walter H. Harris and Mr. Carleton, the interpreter, were informed by a cherif from Taflelt, cousin of the Sultan, and Governor over an extensive district, that there is no question as to the existence of dwarf tribes down the Dra, where they are very numerous. Sir Euan Smith was told of this statement, and probably had a talk with him. Mr. Harris intended to have taken a trip down the Dra to Akka, but was convinced from what he heard that such a trip would be an act of suicide. He however believes that he can get full information as to the dwarfs, and perhaps photographs, without going so far, and he has just left for a trip to the interior for two months. Herr E. G. Donnenberg, who has been for some years engaged in pushing German trade in Morocco, and every year visits the principal cities, says that a year ago he saw in Morocco city from half a dozen to a dozen dwarfs, one of whom was accompanied by a dwarf wife. They were about 4 ft. high, and robust and well made, and were certainly not Moors who had been dwarfed by rickets, as they differed from the ordinary population of Morocco in appearance. Herr Donnenberg's address is Tangier, and he states that he is ready to answer any queries that may be sent to him, but that he cannot add anything to what is here stated, as he did not ask any questions as to the dwarfs, not knowing that they were of interest. He goes to Morocco city before long, and will make it a point to find out all he can respecting them

DURING the latter part of last week a depression lay over the North Sea, which spread both in size and intensity, causing strong northerly winds all over this country, with heavy gales and snow-fall in Scotland and the east of England, while in the southern districts the weather was fine and bright. The temperature was unusually low for the time of year, the mean temperature having in fact been considerably below the average on each day since the beginning of the month. The daily maxima have varied from 40° in the north to 52° in the south, with sharp frosts at night. On Sunday night the grass thermometer in London fell to 20°, while 25° in the shade were registered the next night in the north and west. During the early part of the present week, the area of high pressure in the west gave place to a depression, which arrived from off the Atlantic, causing cold easterly winds in the south with very heavy rains in the south-west of England, the weather over Scotland improved, although some snow showers continued to fall on the east coast. The *Weekly Weather Report*, issued on the 22nd instant, showed that the temperature of that week was much below the mean, the deficit ranging from 5° to 7°. Rainfall exceeded the mean in the east and north-east of England, but in all other districts there was a deficit. In the south-west of England there was still a deficit of about eight inches since the beginning of the year.

WE recently drew attention to a new meteorological journal published in Paris, we now note the appearance of a similar publication at Vilafranca del Panadés, in Spain. It is published on the 15th of each month, and contains a series of short elementary articles and notes, occupying only twelve small octavo pages. We hardly expect it to find many readers in this country, but hope it may awaken more interest in the subject in Spain, where practical meteorology is not at present on the same level as in other European countries.

THE Director of the Lyons Observatory, M. C. André, has published, under the title, "Relations des Phénomènes Météorologiques déduites de leurs Variations Diurnes et Annuelles," the results of the meteorological observations taken there for ten years ending 1890. The text and plates together occupy one hundred and sixty-eight large octavo pages, and this volume will be found to be full of interest and instruction, to any one wishing either to take observations or to work up

the results. The title is well chosen, for the work treats of the relations which connect the different phenomena, it also gives all necessary precautions for ensuring the accuracy of the observations. Particular attention is paid to the important subject of diurnal and annual variations of the different elements, and to the various points to be noted, while the different theories of atmospherical electricity are explained at considerable length.

A BEAUTIFUL and instructive lecture experiment, illustrative of the conditions of the heated atmosphere which give rise to the mirage, is described by MM. J. Macé de Lepinay and A. Perot, in their "Etude du Mirage," which appears in the *Annales de Chimie et de Physique*. Water is poured into a long rectangular trough with glass sides, and covered with a layer of alcohol about 2 cm. thick, containing a trace of fluorescein. After a few hours, during which the alcohol diffuses slowly through the water, a flat beam of light is sent through the mixture at a very slight inclination to the horizon. Under these conditions a kind of garland of light is seen to traverse the liquid, due to a series of curvilinear deflections or "mirages" in the less highly refractive water below and total reflections at the upper surface of the alcohol.

PROF. W. CROOKES and Prof. W. Odling, in their report on the London Water Supply for the month of September, are able to give an excellent account of the 182 samples which they analyzed. All were found to be perfectly clear, bright, and well filtered. In respect to the smallness of the proportion of organic matter present, the character of the water furnished by the seven companies continued to be entirely satisfactory, the mean amount of organic carbon in the Thames derived supply, for example, being 118 part, and the maximum amount in any single sample examined being but 145 part, in 100,000 parts of the water—numbers practically identical with those of the previous month, or 115 part for the mean, and 152 part for the maximum amount. The average of the past six months, in the case of the Thames derived supply, has amounted only to 116 part of organic carbon in 100,000 parts of the water, with a maximum, twice met with, of 152 part in any individual sample. The authors of the report do not expect that with the coming on of autumn and winter this low average will be much longer sustained. They note that the water supply to London is habitually at its best during the hot season, when a high quality of the supply is more especially called for.

AN interesting report on the Congress of the Library Association of Great Britain, held at Paris last month, was read on Tuesday before the Salford Royal Museum and Free Libraries' Committee. It was prepared by Mr. Alderman W. H. Bailey, who had naturally a good deal to say about the Paris Free Libraries. The governing bodies of almost all these institutions consider that there are many reasons why the libraries should be closed in the daytime when respectable artisans are engaged in earning their living. Books are therefore given out for two hours every evening of week days, generally from eight to ten o'clock, and also for two hours every Sunday morning. Mr. Bailey and the other members of the Congress were delighted with the Paris Libraries of Industrial Art, to which they devoted much attention. These Libraries—which, like the Free Libraries, are under municipal control—are in the artisan districts of Paris. Books, patterns, prints, drawings, and photographs are lent out. "Not only do house decorators," says Mr. Bailey, "find designs and books relating to work, but fan painters, porcelain modellers, designers of iron and bronze gates, medieval metal workers, cabinet makers, builders, and all workers in the constructive as well as the decorative arts may here find stimulus and draw inspiration from the wealth of examples on the shelves and walls." Free lectures are delivered in the winter on industrial art and science, and on the designs, books, and models in the Libraries.

VARIOUS experiments which are being made in France with a view to the improvement of the potato have attracted a good deal of attention in Australia. According to a statement recorded in the *Agricultural Gazette of New South Wales*, no fewer than 110 growers have obtained from a variety known as "Richter's Emperor," from twelve to twenty tons per acre, while the average is over fourteen tons to the acre. The Minister of Agriculture in New South Wales has approved of one hundred-weight each of this and any other three sorts highly reputed in France being imported for experimental purposes.

At a recent meeting of a society of French agriculturists, it was stated by Baron Bertrand-Geslin, that ten or twelve years ago a disease appeared among the chestnut trees in central and north western France, and destroyed them in great numbers. The wood, moreover, could not be utilized for heating purposes. At this juncture an enterprising person appeared, who bought up large quantities of this dead wood and sent it by canal to Nantes, where he had works established for utilizing it in the tanning of leather. Chestnut wood contains, in fact, 5 to 6 per cent. of tannic principles, whereas oak contains only 3 or 4. By the means adopted in these works the principles are concentrated in a sirupy liquid of great strength. This establishment has become very important, it absorbs annually thirty to thirty-five million kilogrammes of wood of these dead chestnuts from three departments traversed by the canal from Nantes to Brest, and expends about 120,000 francs per annum, a considerable reduction of the loss sustained by the landowners. It was mentioned, however, by M. Paul Bécquerel, in reply to a question as to competition of the new extracts with bark, that those extracts, which are products allied to tan, do not give the same results, or leather of such good quality, and many tanners who have used them have returned to the old methods of tanning.

DR. R. MUNRO contributed to the *Times* of Monday a long and most interesting account of the recent discovery of an ancient lake-village in Somersetshire. The site is about a mile north of Glastonbury. Before excavations were begun, there were sixty or seventy low mounds, rising from one to two feet above the surrounding soil and measuring from twenty to thirty feet across. That the mounds were of archæological interest was first suspected by Mr. Arthur Bulleid, who began to excavate some of them during the present summer, and was soon rewarded by making striking discoveries. Woodwork corresponding to that of the crannogs of Scotland and Ireland has been exposed, and among the objects which have been recovered are some of bronze, a few of iron, and various specimens of pottery. Mr. Bulleid has also dug out "a splendid canoe neatly formed out of the trunk of a tree." This was found about a quarter of a mile from the settlement. It would seem that the inhabitants, after a period of long occupancy, indicated by a succession of superimposed hearths, were flooded out of their homes, for an accumulation of flood soil now covers the whole meadow to the extent of 12 inches to 18 inches in depth. The surrounding district is richly cultivated, but, in looking over an old map of the date of 1668, Dr. Munro found that it contained a lake called the "Meare Poole," into which three streams debouched, and from which the site of the present discovery could not be far distant. He suggests that this lake had larger dimensions in earlier times, and that when the settlement was founded the locality was a shallow lake or marsh. The old map represents the district lying immediately on the north-west borders of the "Meare Poole" as inhabited by the Belgæ. Dr. Munro is strongly inclined to think that the settlement belongs to the so-called Late Celtic period. Thus he would simply call the Celtic period, for there is no evidence, he believes, of earlier Celtic remains in Britain.

than those known as Late Celtic. "The style of art," he says, "which controlled the manufacture of Late Celtic objects involves such an enormous advance in metallurgical skill over that of the Bronze Age, that it is impossible to suppose the two are connected by any evolutionary stages in this country. From the standpoint of archaeological research this interval, or rather hiatus, can only be bridged over by the supposition that the people who owned Late Celtic remains were newcomers and conquerors in Britain." Much light will no doubt be thrown on the question by the further exploration of these remarkable mounds.

A LIVELY correspondence on the subject of birds *versus* insects has been going on in the Malta papers. According to the *Mediterranean Naturalist*, the enormous increase of insectiferous pests during the last few years has caused the agricultural industries to decline to an alarming extent, and it is urged that the evil has now increased so much as to call for legislation. In the Maltese Islands there are no laws for the protection of birds, and, the lower classes of the Maltese being keen sportsmen, no opportunities are allowed to either the migratory or the indigenous species of increasing.

IT was observed by Prof Voit that when dogs were fed exclusively on bread they daily lost albumen, though not weight, the body becoming more watery and the hæmoglobin of the blood diminishing. This matter has been recently further investigated in his laboratory by Herr Tsuboi. Of three rabbits, one was fed with milk, rolls, and some hay, another with much hay, the third with potatoes. The last had more water in muscles and blood, and less hæmoglobin than the first. In another experiment (with like results) one of two cats was fed with meal and fat, another with bread and some meat extract. Again, three rabbits were fed with potatoes, the first with iron added, the second with serum, the third with blood. The last was found to have most solid matters in muscles and blood, and most hæmoglobin. It is not (the author points out) the amount of food by itself alone that determines the result; otherwise, in the fasting state, the hæmoglobin would be least, whereas it is the same as with good feeding. It is rather the insufficient composition of the food, the too small amount of albumen, with excess of starch-flour that has the injurious effect.

THE phosphoroscope of Becquerel is a well-known instrument, enabling one to observe the phosphorescence of some substance when the exciting light is gone. It is designed to be used with sunlight. M. Lenard has devised an instrument (*La Nature*) for use with the electric spark. To the armature of a Foucault interrupter in an induction coil, is attached a light wooden rod, having at its end a piece of blackened pasteboard, which is thus driven up and down before a spark-interval between two brass knobs connected with the coil and a condenser (added to intensify the spark). The body to be examined is placed close behind the interval, so that it is uncovered very quickly after the spark passes. Some curious phenomena are observed. The short duration of the spark makes the screen seem at rest, and some thousandths of a second after one sees a luminous body behind where it was, so that at first sight one might think the screen opaque to the spark, but transparent for the phosphorescent light, an illusion due to the persistence of luminous impressions. Some bodies, such as various carbonates of lime, behave very much alike in this apparatus and in Becquerel's, some are favoured in the latter, and on the other hand, crystals of arragonite, which are invisible after solar illumination, give a faint reddish light after the spark. Various experiments are described. The most curious results are furnished by the remarkable substance, asaron. In a Crookes tube this gives a bright light, it gives also a distinct glow in the ultraviolet spec-

trum of the spark, but in the phosphoroscope it is absolutely dark. The vibratory movement ceases immediately with the excitation.

THE new number of the *Internationales Archiv für Ethnographie* (Band v., Heft 4) consists mainly of the first part of what promises to be an elaborate paper (in German) on the inhabitants of the Nicobar Islands, by Dr W. Svoboda. In October, 1886, while the German corvette, *Aurora*, lay in the harbour of Nangeauri, Dr Svoboda had many opportunities of seeing the natives, and Mr F. H. Man gave him facilities for the thorough study of a splendid collection of ethnographical objects from various parts of the group. Afterwards he extended his knowledge of the subject by reading books which dealt with it, and by visiting the ethnographical museums of Berlin and Vienna. The results he is now bringing together, and those of them embodied in the present contribution show that he is not only a good observer but that he knows how to state facts clearly and concisely. The paper is illustrated with coloured plates and woodcuts.

THE British Institute of Public Health has now an official quarterly journal, called *The Journal of State Medicine*. It is published by Charles Griffin and Co. The second number has appeared, and contains original papers on the following subjects—lead in articles of food, by Prof. William R. Smith, points in the ætiology of typhoid fever, by Edmond J. McWeeney, chemical bacteriology of sewage, by W. E. Adeney, and new method of sewage purification, by W. Kaye Parry.

A NEW and revised edition of the late Prof. Moseley's well-known "Notes by a Naturalist on H. M. S. *Challenger*," has been issued by Mr John Murray. It includes an excellent portrait, which vividly reminds us of the great loss inflicted on science by his premature death.

MESSRS WHITTAKER AND CO. have published the first part of a work entitled "Dissections Illustrated. A Graphic Handbook for Students of Human Anatomy," by C. Gordon Brodie. The plates are drawn and lithographed by Percy Highley. The work will be completed in four parts. The present part deals with the upper limb, and includes seventeen coloured plates.

A SECOND edition of "A Short Manual of Inorganic Chemistry," by Dr A. Dupré and Dr H. W. Hake (Charles Griffin and Co.), has been issued. The authors have endeavoured to bring the statement of facts up to date without increasing the bulk of the work, and to remove those errors to which their attention has been drawn.

A RE-DETERMINATION of the mechanical equivalent of heat has been made by M. C. Miculescu at the Sorbonne. An account of the method appears in the *Annales de Chimie et de Physique* for October. The method was that of water friction at constant temperature. The liquid was enclosed in a cylindrical vessel with three envelopes. Water was kept circulating round the innermost one at such a rate that the difference of temperature of the water at entrance and exit was constant as measured by a thermopile. The heat thus derived from the water inside could be estimated by the quantity of water passed through. The water inside was stirred by vanes mounted on an axial shaft kept rotating by a gramme machine of 1 horse power running at 1200 revolutions per minute. The expenditure of work was measured by making the whole apparatus its own dynamometer. It was suspended so as to turn round the common axis of the stirrer and the motor. The resistance met with by the former tended to turn the apparatus in the direction of revolution of the latter. It was kept stationary by a weight attached to an arm exerting a measurable couple. The mean of 31 values ranging from 425.21 to 427.12 was 426.70 in kilogram-metres

per calorie, or  $4.1857 \times 10^7$  ergs. For the normal scale of the hydrogen thermometer this would be 426.84.

A NEW and very convenient method of preparing acetylene gas is described by M. Maquenne in the current number of the *Comptes Rendus*. A short time ago the same chemist succeeded in preparing a comparatively stable compound of carbon with the metal barium,  $\text{BaC}_2$ , by heating powdered retort-charcoal with barium amalgam in a current of hydrogen. Upon bringing this compound in contact with water a violent action was found to occur with evolution of almost pure acetylene gas. On account, however, of the troublesome nature of the operations of procuring barium amalgam and preparing from it the new compound, together with the very small quantities of the latter eventually obtained, this mode of preparing acetylene was only of theoretical interest, and not suitable as a laboratory method of preparation. M. Maquenne now describes a new process for preparing barium carbide, by means of which large quantities may very readily be procured in a few minutes, and from which correspondingly large volumes of acetylene may be derived. The principle of the method consists in reducing barium carbonate by metallic magnesium in presence of carbon. An intimate mixture is first made of barium carbonate prepared by precipitation, powdered metallic magnesium, and calcined retort-carbon. Convenient amounts are twenty six grams of barium carbonate, ten and a half grams of magnesium, and four grams of charcoal. This mixture is then introduced into an iron bottle of about seven hundred cubic centimetres capacity, furnished with a tube, also of iron, thirty centimetres long and two centimetres internal diameter. The iron bottle is then heated in a gas furnace which has previously been raised to a red heat. At the expiration of about four minutes an energetic reaction occurs, accompanied by the projection of brilliant sparks from the mouth of the tube. The apparatus should then at once be removed from the furnace, the end of the tube stopped, and the bottle and contents rapidly cooled by the external application of cold water. The product may then be extracted, when it is found to consist of a mixture of magnesia with 38 per cent of carbide of barium, a little excess of carbon, and a trace of cyanide formed at the expense of the atmospheric nitrogen. The reaction accords very closely with the equation —

Carbide of barium may be preserved for an indefinite time in a dry atmosphere. It is a grey, porous, and very friable substance. When heated to redness in the air it burns with a vivid incandescence. It is also capable of combustion in chlorine, hydrochloric acid gas, and vapour of sulphur. In order to prepare acetylene from it the powder is most conveniently placed in a small flask fitted with a doubly-bored caoutchouc stopper, carrying a dropping funnel containing water, and a delivery tube. The moment water is allowed to drop the equivalent quantity of acetylene gas is evolved in accordance with the equation —

The delivery of the acetylene may be regulated with great nicety by suitable adjustment of the stopcock of the dropping funnel. The acetylene thus prepared possesses the further advantage of being remarkably pure, containing 98 per cent of  $\text{C}_2\text{H}_2$ . It is interesting to learn that by allowing a stream of this pure acetylene to pass through a long heated glass tube for a few hours several grams of synthetical benzene have been accumulated by M. Maquenne.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ?) from India, presented by Mr W. F. Faulding, a Buffon's

Touracou (*Corythaix buffoni*) from West Africa, presented by Mr A. L. Jones; two Double banded Sand Grouse (*Pterocles bicinctus* ♂ & ♀) from Senegal, presented by Mr H. H. Sharland, F.Z.S., a Gannet (*Sula bassana*), British, presented by Dr Davis, a Roseate Cockatoo (*Cacatua roseicapilla*), a King Parakeet (*Apromictus scapularis* ?) from Australia, presented by Mrs Addiscott, four Alligators (*Alligator mississippiensis*) from the Mississippi, presented by Mr John Terry, two Thick billed Seed-eaters (*Oryzoborus crassirostris*), a Tropical Seed Finch (*Oryzoborus torridus*), a Saffron Finch (*Scytalis flaveola*), a Bluish Finch (*Spermophila caerulea*) from South America, a Puff Adder (*Varperia arietans*) from West Africa, deposited

## OUR ASTRONOMICAL COLUMN

COMET BARNARD (OCTOBER 12). — An *Astronomische Nachrichten* circular note gives the following elements and ephemeris, computed from observations made on the 16th, 17th, and 18th of this month —

### Elements

T = 1892 Nov 12.745 Berlin M.T.

$$\omega = 168.49$$

$$q = 220.50$$

$$i = 21.39$$

$$\log q = 0.03669$$

### Ephemeris Berlin Midnight

1892	R.A. h m	Decl. ° ' "	Log Δ	Br
Oct 25	20 6.6	+7 47		
27	13 5	6 51	9.6825	1.46
29	21 5	5 52		
31	29 8	4 51	9.6609	1.66
Nov 2	38 7	3 47		
4	48 2	2 40	9.6377	1.87
6	20 58.3	1 29		

As the brightness at the time of discovery is taken as unity, it will be noticed that the comet is quickly gaining in intensity, the value for November 8 being 2.08 Br. Its position on the 31st lies in the southernmost part of the constellation of the Dolphin, forming very nearly an equilateral triangle with α Aquilæ and β Delphini.

DISCOVERY OF THREE NEW PLANETS BY PHOTOGRAPHY. — M. Perrotin has communicated to the French Academy an account of the discovery of three small planets by M. Charlois, of the Nice Observatory, by the aid of photography. The apparatus employed consisted of an Hermagis portrait lens of 15 cm aperture and 80 cm focal length, mounted provisionally on M. Loewy's equatorial clock. The instrument was being employed for the photography of the region of the ecliptic. With exposures ranging from two hours and a half to three hours, the eight negatives obtained since September 12 cover a region 80° long and 10° broad, and show all the stars visible through the 38 cm refractor. A careful examination of the plates reveals the presence of three unknown and eight known planets. The former, now known under the names 1892, D, E, and F, are all of about the twelfth magnitude.

RUTHERFORD MEASURES OF STARS ABOUT β CYGNI. — Mr Harold Jacoby, in No. 4 of the *Contributions from the Observatory of Columbia College, New York*, presents us with the reduced results of the measures of the plates containing the group of stars surrounding β Cygni. The method of measurement was exactly the same as that employed in the case of the Pleiades plates, but that of reduction has received some slight modification. For instance, the measures of the eastern and western impressions have not been separately dealt with, but their mean has been taken, and the reduction continued, using this mean as a single observation. As the accuracy of these measurements depend on the exactitude of the scale value determinations to a very considerable extent, it is satisfactory to hear that this value has remained materially the same for a very long period. The largest and smallest values recorded in the Pleiades plates were 28" 0167 and 28" 0066, the mean value amounting to 28" 0124, and it is

his last-mentioned value that has been used in the above reductions. The probable error of these determinations is then  $\pm 0.00071$ , which corresponds to  $\pm 0.025$  per 1000. But Mr Jacoby does not think that the average uncertainty of the final places exceeds  $0.15$  on account of scale value. While comparing the Rutherford stars with those of Argelander, he found that four stars from the latter were lacking, while they were recorded on the original negatives of the former. Observations made this year showed that three were visible, while the fourth (No 28), which was quite close to No 27 on the Rutherford negatives, was this year "only a sort of elongation of No 27." On the other hand, the following of Argelander's stars were absent from the plates —

B D	+ 27 3395	Mag	8 8
	+ 27 3414	"	9 0
	+ 27 3417	"	9 0

and perhaps

	+ 27 3435	"	8 5
	+ 28 3343	"	9 0

A NEW VARIABLE STAR.—In *Astronomische Nachrichten*, No. 3124, Prof Pickering announces the discovery of a new variable star in Aries by Prof Schreberle. The fact of this star being a variable was first noted when, on an examination of two plates taken December 18 and January 24, 1891, it was found that on the former it appeared of the 9.5 magnitude, while on the latter it was absent altogether. Recent visual observations have shown, however, a star of the eleventh magnitude in the exact position of the suspected variable, and this has been confirmed by means of photographs. From photographs of the same region, taken since October 31, 1890, the magnitudes recorded have been 9.6, 10.2, 11.0, less than 11.7, 10.1, 10.0, 10.4, 10.3, and 10.9. The star's position for 1900 is given as

R A 3h 55m Decl + 14°24'

JUPITER'S FIFTH SATELLITE.—It hardly ever happens that, after a discovery of any importance has been made, there are not a few "claimants" who wish to annex it as their own. This is the case with Prof Barnard's discovery of the fifth moon to Jupiter, but the advantage he possesses over these said "claimants" is, we might say, infinite, for it is only with such an instrument as that at the Lick Observatory that this "mite" of a satellite can be observed with success. One of the despatches in which one "claimant's" views were put forth, had the audacity to insinuate that Prof Barnard was directly inspired to this discovery by information contained in a letter sent to the Observatory. We are glad to see that Prof Barnard deals with these "claimants" as they deserve, and we hope it may be a lesson to others who wish to assert their priority without good and sufficient reasons for doing so.

As an illustration of the difficulty of observing this satellite, we may mention that Prof Young, in a letter to Prof Barnard, says that although he has used a 23 inch Clark, which is an instrument as nearly perfect as can be made, he was not rewarded with success.

THE SPECTRUM OF NOVA AURIGÆ.—Herr E. von Gothard, of the Observatory at Herby, has taken a very successful photograph of the Nova spectrum, the results of which he communicates to *Astronomische Nachrichten*, No 3122. The instrument used was a 10½-inch reflector with a 10-inch objective prism, and the exposure given amounted to 45 minutes. The spectrum shows six lines, and a comparison with the spectrum of the ring nebula and the Wolf-Rayet stars presented a remarkable concordance, the first failing only in the second Nova line, and the second differing only with regard to the intensity of the individual lines. The following table shows this somewhat more clearly —

	I	II	III	IV	V	VI	VII
Nova	6	1	10	5	3	4	—
G. C 4964	8	2	10	6	6	8	—
Ring nebula	8	—	5	2	7	6	10

The wave lengths of the lines are, we are sorry to say, not inserted.

"JUPITER AND HIS SYSTEM" is the title of a small book recently published by Mr Stanford, and written by Miss E. M. Clarke. The authoress has brought this book out at a time when this planet is receiving most attention, for was it not in opposition, shining with exceeding brightness, on the 12th of this month? One great point about this little monograph is

NO 1200, VOL. 46]

that facts throughout have been strictly adhered to, so that the reader is presented with the true state of the planet as we know it. The information is well up to date, as for example the mention of the new satellite, and the book is written in a popular yet accurate style. One thing that calls for attention is the price (one shilling), which could doubtless have been halved.

## GEOGRAPHICAL NOTES

MR J. Y. HUGHANAN, F.R.S., is this term delivering a course of lectures on Oceanography in Cambridge University. It is satisfactory to know that the lectures are better attended than has been the case since the foundation of the Geography lectureship, and that the greater number of those present this term are undergraduates.

MR JOSEPH THOMSON has submitted to the British South Africa Company the report of his journey to the Lake Bangweulu region, made last year, which ill health has prevented him from preparing sooner. He speaks of Northern Zimbesia generally as a region of great possibilities. It is a plateau rarely less than 3500 feet high, with a climate in which Europeans should find no difficulty in living for several years at a time. It is well suited for cattle rearing and for planting, and there is an appearance of mineral wealth. Like the rest of tropical Africa, the land must be occupied and cultivated, and the natives must be trained to industry before commercial results of any importance can be obtained.

THE special meeting of the Royal Geographical Society to hear Captain Lugard's paper on Uganda will be held on Thursday, Nov 3, at 8.30 p.m. On account of the great popular interest at present being manifested in the region of the Equatorial lakes, no extra tickets can be issued by the Society, as the attendance of Fellows and their friends will probably more than fill the hall.

THE new number of *Petermann's Mittheilungen* contains some articles of considerable interest. Dr W. Ruge, son of the well-known geographer, Dr Sophus Ruge, contributes a short but learned treatise on the geography of Asia Minor, which combines literary research with personal exploration. Dr Ernst H. L. Krause produces an interesting map of North Germany, showing the distribution of forests and the most common species of trees during the Middle Ages. This work is accomplished mainly by the consultation of old records, and the examination of the remains of old forests and very ancient trees. The study of history is greatly helped by such a map, and the influence of increasing density of population and extending cultivation of farm crops is brought out strikingly by comparison with a map of the vegetation at the present day. Dr Karl Sapper's description of Lake Yzabal in Guatemala is also worthy of note.

## GEIKIELITE AND BADDELEYITE, TWO NEW MINERAL SPECIES

VARIOUS pebbles were lately brought to this country by Mr. Joseph Baddeley, who has been acting as manager of a Gem and Mining Company in Ceylon. They had been picked up by him in the neighbourhood of Rakwana (Rakwanna) at various times, and had then attracted his special attention by reason of their high specific gravity. Their real nature not being evident on inspection, Mr Baddeley, when invalidated, brought them home to England for identification.

One kind of pebble, kindly analyzed for him by Mr. Claudet, was found to be essentially a tantalate of yttrium.

Pebbles of another kind were taken to the Museum of Practical Geology in Jermyn Street for examination. The external characters being found by Mr. Pringle insufficient for the determination of the species, the pebbles were handed over to Mr. Allan Dick for chemical investigation. Quantitative analysis proved the mineral to be essentially magnesium titanate ( $MgTiO_3$ ) and chemically analogous to Perovskite, calcium titanate ( $CaTiO_3$ ). To this interesting new species Mr. Dick, in a paper read before the Mineralogical Society in June, gave the name Geikielite, in honour of Sir Archibald Geikie, F.R.S., Director General of the Geological Survey, in whose laboratory the analysis had been made.

As described by Mr. Dick, Geikielite has a specific gravity

398 its hardness (6.5) is between that of quartz and felspar. It has a perfect cleavage, with a splendid metallic lustre, and an imperfect cleavage nearly at right angles to the former. The pebbles themselves show no remains of crystal-faces, are bluish-black in colour, and opaque, but thin cleavage-flakes, when seen in the microscope, have a peculiar purplish red tint, and in convergent polarized light show a uniaxial figure, of which the axis is just outside the field of vision. When digested with hot strong hydrochloric acid the finely powdered mineral is slowly decomposed, and the titanous acid separates out. In strong hydrofluoric acid complete solution takes place in a few hours. The mineral is infusible with the blowpipe fused with microcosmic salt it gives the characteristic reaction of titanous acid, notwithstanding the presence of a small proportion of oxide of iron.

Shortly after Mr. Dick's paper had been read, Mr. Baddeley courteously offered to allow me to select a single pebble for the British Museum Collection out of his small store of the mineral, the remaining ones being required by him for sending as samples to be used by searchers in Ceylon. But this store, small though it was, consisted of more than one kind of pebble, the close similarity of aspect being due to friction against a bit of graphite which was with them. On this heterogeneity being pointed out, Mr. Baddeley allowed me to take not only the promised pebble of Geikielite, but also those three pebbles which, not being Geikielite, were useless as samples of that mineral. One of the three fragments proved to be garnet, a second was ilmenite—both of them common minerals—but the third, a fragment of a crystal still retaining some of its faces, presented characters which give it unusual interest.

The fragment, which weighs just over three grains, is black and opaque, and has the general aspect of columbite, its extremely high specific gravity (6.02) and its hardness (6.5) are also suggestive of that mineral. In microscopic fragments it transmits light and is dichroic, changing from a greenish yellow to brown with the plane of polarization of the light, the fragments, when examined in convergent polarized light, show a biaxial figure, the apparent axial angle being large (near 70°), the character of the double refraction is negative. There is only one well developed zone of crystal faces remaining on the fragment, it consists of two rectangular pairs of parallel faces (pinakoids) and of four prism faces (*m*), the faces of one pinakoid (*a*) being much larger than those of the other (*b*), the angle *am*, as determined by means of reflection, is about 44°, but the images of the signal are multiple and wanting in definition, the dispersion of the optic axes indicates that the system of crystallization is mono symmetric. Two other faces form a re-entrant edge parallel to the larger pinakoid, and inclined to the edges of the well developed zone, but whether this is really due to twinning or not is far from evident.

The above set of external characters suggested that the fragment does not belong to any of the known species, and it became necessary to determine its chemical behaviour, but on account of the necessity of preserving the natural faces of what might possibly be an unique fragment, this was a process demanding great caution, fortunately, the behaviour was such that it was practicable to determine the precise chemical nature of the mineral without interference with the crystal faces, or, indeed, any appreciable destruction of material. It will be sufficient to state here the result, namely, that the material is no other than crystallized zirconia, the technical details relative to both this mineral and Geikielite will be given in the next number of the *Mineralogical Magazine*. It is remarkable that, notwithstanding the wide prevalence of zircon itself (silicate of zirconium), the natural occurrence of the oxide of zirconium has not previously been noticed. For this new species I beg to suggest the name Baddeleyite, in recognition of the services of Mr. Baddeley to mineralogical science, but for his close scrutiny of the mineral products of Rakwana, the existence of the above remarkable species would doubtless have long remained unknown.

L. FLETCHER

### NEW BRITISH EARTHWORMS

THE additions which I have been able to make to our list of indigenous Annelids during the past two years fall naturally into two groups. There are, first, two species which are new to science, and are therefore at present known only as British species. In addition to these there are several species which, while they have been recorded for various Continental stations,

have never been found in England till I discovered them among the gleanings which I have passed under review from nearly every part of the country. I shall first of all give a description of the new species.

#### 1. *Lumbricus rubescens*, sp. nov.

This is a genuine *Lumbricus* in the strictest sense of the word, as it is understood by all those who adopt Fisen's analysis of this group of worms published in 1873. The lip forms a perfect "mortise and tenon," with the first ring or peristomium, and the girdle consists of six segments, four of which bear the *tubercula pubertatis*. I first discovered it in Yorkshire in 1891, and have since then taken it myself at Hornsey in Middlesex, Tunbridge Wells, and Dallington in Sussex, while more recently I have received it from Avonmouth in Gloucestershire.

In general appearance it resembles the common earthworm (*L. terrestris*, L.), as recently defined and differentiated. It is slightly smaller in size, but frequents similar haunts, and might in most respects easily be mistaken for the type. It has the male pores on segment 15 on raised, pale papillæ, but the girdle invariably commences on segment 34, and extends to the 39th, while the band which forms the *tubercula pubertatis* extends over 35 to 38. Its general form and appearance will

FIG. 1.—*Lumbricus rubescens*, Fien. Natural size.

be best understood by the study of the woodcut (Fig. 1). Internally it does not differ from the other *Lumbrici*, but the dorsal pores commence between  $\frac{1}{2}$  and  $\frac{1}{3}$ . This makes the fourth true *Lumbricus* found in the British Isles, and it may be a convenience to collectors if I append a tabular statement of the features by which each is distinguished from the other.

#### Chart of the Genus *Lumbricus*

Lumbricus	Segments occupied by the					Average length	No. of segments
	Girdle	Tubercula	First dorsal pore	Papillæ	Spermatophores		
<i>Terrestris</i> , Linn.	32-37	13-30	1	15, 26	9	5 inches	157-200
<i>Rubescens</i> , Fien.	44-49	35-38	1	15, 28	32-33	4 inches	120-150
<i>Rubellus</i> , Hoffm.	27-32	28-31	1	n. n.	1	3 inches	110-140
<i>Purpureus</i> , Eisen.	28-31	29-32	1	10 (11)	1	2 inches	100-120

It will be seen that there is now a regular series in relation to the first dorsal pore,  $\frac{1}{2}$ ,  $\frac{1}{3}$ ,  $\frac{1}{4}$ ,  $\frac{1}{5}$ , as well as in the matter of length from 2 to 5 inches and upwards, and number of segments from 100 to 200 or thereabouts. These points are worthy of note in the study of the evolution of worms.

#### 2. *Allolobophora cambrica*, sp. nov.

This species, which I have since found in several parts of England, first came to my notice as a new species from Wales. Hence the specific name. I had previously assigned it to one or other of the related species, but eventually found on dissection that it was quite distinct from every other worm of which I have been able to obtain any description.

At first sight *A. cambrica* has all the appearance of the mucous worm (*A. mucosa* Eisen). Its average length in spirits is about 2 inches, but when living, and moderately extended, it measures three inches. It is of a fleshy colour, with a somewhat transparent skin, so that the blood vessels can be well observed between the girdle and the head. The dorsal pores are conspicuous in specimens which have been placed in methylated spirits, the first occurring between segments 4 and 5. The

Vejdovsky and others mention the occurrence of Spermatophores on these species, but do not state the position. The point is one which should not be ignored.

setae are in four couples, the individuals of which are near each other. The girdle covers segments 29 to 37, while 31 33 35 bear each a pair of tubercles (Fig 2) as in the green worm

FIG 2.—Diagram of girdle of *A. cambrica*, Friend, showing tubercula on ventral surface

(*A. chlorotica*). There are two pairs of spermathecae in segments 10 and 11, opening anteriorly, the male pore on segment 15 is borne on prominent papillae, which cause the adjoining segments to appear swollen (Fig 3). It is a very clean worm,

FIG 3.—*Allolobophora cambrica*, Friend. Natural size

exudes but little mucus as compared with the green worm, the tail is much longer than in that species, which, in the matter of girdle and tubercles, it most nearly resembles. It will be well to tabulate the points in which this worm resembles and differs from its nearest allies

*Allolobophora cambrica* resembles

<i>Allo. chlorotica</i>	<i>Allo. mucosa</i>
in position and appearance of male pore, girdle, and tubercula	in colour, shape, size, activity, position of first dorsal pore, and appearance of male pore
<i>pubertatis</i>	

It differs

in mucus, transparency, length and shape of tail, and number of spermathecae	in position and shape of girdle, position of tubercula, position of first dorsal pore, and general outline
--	--

#### Tabular View

Allolobophora	Segments occupied by the				General observations.
	Girdle	Tubercula	First dorsal pore	Spermathecae	
Chlorotica	29-36	31 33 35	1	9 10 11	Dirty green, opaque, sluggish, and grub-like, exudes much mucus
Mucosa	26-34	29 30 31	2	10 11	Flesh coloured active, with transparent epidermis little mucus
Cambrica	29-37	31 33 35	1	10 11	Closely resembling <i>mucosa</i> in general features

When our knowledge of the hybridity of worms is more perfect, it is possible that some new light will be thrown upon such coincidences as these. I have received the worm from, or collected it in, Nottinghamshire, Hertfordshire, Yorkshire, and Montgomeryshire. I believe I have also found it in Westmorland and elsewhere, but entered it either under one or the other of the two species which it so closely resembles.

Next, we have to note the worms which are new to Britain, though not new to science. These all fall under the genus *Allolobophora*, and several of them are so well marked that I have, in some recent articles on this subject, revived Eisen's subgeneric term *Dendrobana*, and placed under it about half a dozen species of tree-worms which are more or less widely distributed in this country.

The tree-worms are small, hardy, and active, the lip is usually very delicate, and appears to be used, not only as a sucker and boring agent, but also as a tissue dissolver, probably by the use of a special saliva. The setae are usually in eight almost equidistant rows, and the lip cuts more or less deeply into the first

ring. The type of this group is *Dendrobana Boeckii*, Eisen, which has been the subject of endless confusion. The true species, following the diagnosis of Eisen, is very rare in England, and I have found it nowhere but in Airedale and Wharfedale, Yorkshire. I believe all the other records which have been given by other writers should be assigned to the much more common and widely distributed species known as *Allolobophora subrubicunda*, Eisen. This worm belongs to the same group, but lives among vegetable debris as well as beneath the bark of decaying trees. Another species (*A. arborea*, Eisen) is found only in dead timber. I have specimens from Cumberland, Gloucestershire, Yorks, and Sussex. It is one of the prettiest and neatest worms indigenous to this country. Nearly related to this is another (*A. celtica*, Rosa), which, while it prefers trees, will thrive among decaying vegetable matter. I first found it at Langholm, N.B., some two years ago, but since then I have taken it plentifully in Carlisle, Morecambe, and Tunbridge Wells, besides receiving it from Sussex, Devonshire, Gloucestershire, Northants, and elsewhere. It bears spermatophores during the spring months.

When I was in the south of England in the early months of this year, I discovered a couple of specimens of a new British tree worm (*A. constricta*, Rosa). This species seems to me to belong to the south, just as *D. Boeckii* belongs to the north. I am making notes on the distribution of these species in order if possible to ascertain their limits. A very anomalous worm (*Lumbricus Eiseni*, Levinson) belongs to this group, though it has certain *Lumbricus* affinities. It is far from being a true *Lumbricus*, since it possesses neither tubercula, pubertatis, nor spermathecae. Its girdle, too, is abnormal, for, whereas in the genuine *Lumbricus* the girdle invariably covers six segments, in this worm it extends over eight or nine. At present it does not fit in to any known genus, and should probably be made the type of a new genus. I have found it in Carlisle, Gloucestershire, and Sussex. Rosa has obtained it in Italy, and Levinson in Copenhagen, so that it appears to be very widely distributed. On the Continent one or two further species belonging to this group are on record. On account of their habits, size, and affinities I place them in the subgenus *Dendrobana*, which may be presented in tabular form as follows:—

#### Tabular View of Subgenus *Dendrobana*

Dendrobana	Segments occupied by the			Setae	Prostomium	Colour
	Girdle	Tubercula	First dorsal pore			
Boeckii, Eisen	29-31	31 32 33	—	8 equidistant	Cuts & peristomium	Dark brown
Subrubicunda, Eis	26-31	28 29 30	3	4 wide pairs	Cuts half one	Rose red, fleshy
Arborea, Eisen	27-31	29 30	3	4 wide pairs	Cuts half one	Red brown, iridescent
Eiseni, Levinson	24-32	0	1	4 close pairs	Cuts whole	the Violaceous iridescent
Constricta, Rosa	26-31	0	3	4 pairs	Cuts half one	Rose red, fleshy
Celtica, Rosa	30-36	33 34	—	4 wide pairs	Cuts half one	Violaceous, ruddy

Another group of worms belonging to the genus *Allolobophora*, with features more or less similar to those of the typical earthworm, has recently been enlarged by the addition of two or three species. The first (*A. profuga*, Rosa) seems to be generally distributed throughout England, as I have received it from several localities. Its synonymy, however, is at present somewhat uncertain. The long worm (*A. longa*, Ude) is the most ubiquitous of all our native species, and has for years past been confused with the common earthworm. The other species must for the present be entered as *A. complanata* (Dugès). The Continental authorities differ in their judgment respecting the identity and synonymy of this worm, and I have hitherto been unable to disentangle the complications. Certain it is that we have a species which corresponds in part with the worm described imperfectly by Dugès, and I hope in a little time to be able to determine its exact relationships.

I append a list of all those species of British earthworms which I have personally collected, examined, and identified, in

each instance referring to the original memoir, and collating the worm with the author's description

When Darwin wrote his work on "Vegetable Mould," he assumed the existence of eight or ten species of earthworm in Great Britain. We now find a score of well defined species, to which I have no doubt we shall be able to add a few others when the montane and out-of-the-way habitats have been explored. I shall be happy to receive consignments of living worms from any part of the kingdom, packed in tin boxes lightly filled with soft moss, and addressed The Grove, Idle, Bradford.

HILDEBRIC FRIEND

*THE PROBLEM OF MARINE BIOLOGY*<sup>1</sup>

IN common with the other branches of biological science, the study of marine life has made wonderful advances in the past half century, and we now begin to get a proper conception of the vastness and importance of this realm of nature.

The study of marine life has been compassed by serious difficulties, on shipboard it is impossible to examine in the living condition the enormous quantity and endless variety of forms brought up at a single haul of the net or dredge, and the old method of merely dropping the specimens into vials of alcohol resulted in vials of wrath to the naturalist who later studied the creatures in hopes of gaining from the distorted relics some knowledge of the normal appearance and anatomy. Now all this is changed, and by aid of certain chemical reagents most animals can be killed and preserved in a manner very satisfactory for study of their gross and microscopical anatomy, and hence the material collected can be examined at leisure in permanent laboratories with results corresponding to the better facilities. There has, too, been a great lack of suitable and accurate collecting apparatus. The early method was to scoop up a quantity of sea water and then tediously examine it in small quantities under the microscope. In 1845 Johannes Müller, the great pioneer of marine biology, conceived the idea of condensing into a small volume of water the forms which would be found in a very great area. This resulted in the invention of the "Müller Net," a small gauze net which is drawn through the water, entangling in its meshes the very minute and delicate or-

ganisms. For a long time Müller and his students pursued the study of marine forms, and at length came the discovery that the marine fauna and flora was directly comparable to the terrestrial.

Yet little is known of the laws of the distribution of marine life. The laws of the distribution of the terrestrial fauna and flora have been formulated for animals in the classical works of Wallace and for plants by Grisebach. The famous Challenger expedition (1873-1876), under the direction of Sir Wyville Thompson and Dr. John Murray, has given us the largest conception of the wealth of marine life, and has laid the foundations for the study of the marine forms both at the surface and in the depths of the ocean. Dr. Murray in his preliminary report called particular attention to the enormous wealth of organic life not only at the surface, but also many hundred fathoms below. He says that when living forms were scarce on the surface the tow net usually disclosed very numerous forms below, even to a depth of 1000 fathoms or more. In the North Pacific Ocean, the discovery was made that zones of definite depth are characterized by animals and plants peculiar to them. The tow nets sunk to 500, 1000, or 2000 fathoms brought up forms never found within 100 fathoms of the surface. The animals characteristic of these different depths are, for the most part, of the class of Radiolarians, those microscopic organisms whose siliceous skeletons form much of the soft ooze which carpets the bottom of the deep sea. Prof. Haeckel, by study of this material, was led, in his monumental work on the Radiolaria, which forms a part of the "Report of the Challenger," to the recognition of three groups, (a) pelagic, swimming at the surface of the calm sea, (b) zonal, swimming in definite zones of depth (to a depth of more than 20,000 feet), (c) profound (or abyssal) animals swimming immediately over the bottom of the deep sea. In general the different characteristic forms correspond to the different zones (up to 27,000 feet).

The existence of this intermediate pelagic fauna was called in question by Alexander Agassiz, on the ground of the liability of error in using the ordinary open net instead of one which could be closed at a definite depth and then drawn up, and more particularly upon the ground of his own experiments made in 1878 on the *Bute* expedition. He believes that the great bulk of the ocean contains no organic life at all, that the surface fauna of the sea is limited to a relatively thin layer, and that there is no intermediate layer, so to speak, of animal life between the fauna of the bottom of the deep sea and of the surface.

Agassiz's results are contradicted by those of Chierchia on the Italian corvette *Letto Pirani*. With the closable net invented by Palumbo he brought up an astonishing quantity and variety of forms of life from different depths, even up to 4000 metres. Prof. Carl Chun, with an improved closable net, studied the marine fauna and flora of the Gulf of Naples. He formulates his results as follows: (1) That part of the Mediterranean in investigated shows a rich pelagic life even to a depth of 1400 metres, as well as at the surface. (2) Pelagic animals, which during the winter and spring appear at the surface, at the beginning of summer seek the depths. (3) At greater depths pelagic animals occur, which hitherto have seldom or not at all been observed at the surface. (4) A number of pelagic animals during the summer remain at the surface and never go into the depths. From his observations upon the vertical distribution of marine life he was led to remark that the surface fauna was apparently only the advance guard of the vast army below. His conclusions were confirmed by observations made during a trip to the Canary Islands, and agree with those made by Prof. Haeckel twenty years before.

Prof. Hensen, of Kiel, has for several years past been studying the phenomena of pelagic life with a view of ascertaining its relations to the fisheries question. He has proposed the term Plankton (from *πλάνωμαι*, to wander) to designate this world of marine life. Prof. Haeckel agrees with this and adds Planktology, that branch of biology which deals with the study of the Plankton. Prof. Hensen hopes to gain valuable information upon the phenomena of marine life by a careful mathematical estimation of the number of individuals in a given bulk of water. Presumably from this and other data some knowledge may be gained of the quantity of life which any definite area of the sea is capable of sustaining.

Prof. Ernst Haeckel, of Jena, has lately published an admirable *résumé* of our knowledge of pelagic life, and has made a very distinct advance by formulating some of the laws which govern its distribution. He has probably done more than any

<sup>1</sup> Reprinted from the *American Naturalist* for October, 1892.

one man to advance our knowledge on this line. Ever since 1854, when, as he tells us, he accompanied the great Johannes Müller to Heligoland and was there introduced by his master to the marine wonderland, he has almost continuously pursued the study of the Plankton. He believes that aquatic life in its broadest features shows conditions of distribution similar to those of terrestrial life, and that we may for the former as well as for the latter distinguish five great geographical provinces, each represented by characteristic forms of animals and plants: (1) the Arctic Ocean, (2) the Atlantic, (3) the Indian, (4) the Pacific, (5) the Antarctic.

All aquatic organic forms fall into two great divisions. (1) Those which live free in the water, either swimming actively or passively floating at the mercy of currents and winds. These compose the Plankton. The Plankton thus includes the widest range of organic size and form, from the minutest microscopic organisms to the gigantic cetaceans. (2) Those forms which live upon the sea bottom, either fixed or creeping about. To these the term *Benthos* (and *Béthos*, the bottom of the ocean) is applied. The variety of forms living near the shore is known to vary with the depth, while the forms characteristic of the comparatively shallow waters of the coasts are widely different from those which inhabit the bottom of the deep sea.

The number and the kind of forms composing the Plankton are found to differ with the quality of the water, i.e. fresh or salt. In the ocean there is a marked difference which is conditioned by the distance from the shores, either of continents or islands. There are many species of animals, particularly certain coelenterates, echinoderms, and worms, which pass only part of their life as free-swimming animals, for the remainder, they are bottom dwellers. Such species are not usually found far from the coast, and hence the true oceanic Plankton is made up of forms which pass their entire life as free-swimming organisms. By the presence or absence of these bottom-dwelling species the Planktologist can determine approximately the region where the forms were captured.

A mere list of the genera, not to mention the species, of plants and animals up to the present found to take part in the constitution of the Plankton would be very formidable. The range in size is enormous, from the exceedingly minute unicellular algae, some of an inch in diameter to the huge bulk of many fishes and cetaceans. The microscopic forms constitute the fundamental food supply in the cycle of marine life. They are capable of exceedingly rapid multiplication, and furnish nourishment for the myriads of large animals, which in time are preyed upon by the still higher forms. The inconceivable number of individuals of the smaller species is demonstrated by Prof. Hensen's determination of the number of individuals in about two cubic yards of Baltic Sea water. This was found to contain 5,700,000 distinct organisms, of these only about 150,000 were visible to the unaided eye. But very often microscopic forms become so numerous as to form a slime upon the surface of the water for a considerable area. Ships frequently sail for miles through water coloured by these microscopic organisms, e.g., the so-called "black water" of the Arctic and Antarctic Seas, is a slime of diatoms, which serve as food for the shoals of minute crustacea and mollusca (Pteropods, sea butterflies, and Cephalopods, squid, cuttlefish) upon which the walrus and whales feed. In the warm regions the inconceivably enormous quantity of diatoms are replaced by another kind of algae, the *Ocellularia*, which often for an area many miles in extent colour the sea a dark red or yellowish brown. The Red Sea received its name from the abundance of one of these algae, *Trichodesmium erythraeum*, which, according to Ehrenberg, coloured the water along the shore a blood-red. In the warm regions also are found the huge floating banks of Sargassum, or gulfweed, forming the so-called Sargasso Seas of the Atlantic and Pacific Oceans. These areas are found to have a marine fauna and flora peculiar to themselves, but approximating in character to that of the coast waters.

The simplest forms of animal life of the Plankton belong to the groups of Infusoria and Rhizopoda, to the latter belong those minute animals, the Foraminifera and Radiolarians, which occur in such enormous quantities that their calcareous and siliceous shells form the "deep sea ooze" which carpets the bottom of the deep sea. It is the shells of these animals, too, which have built the vast chalk beds in various parts of the world. Among the multicellular animals which take a prominent part in this marine world are many species of medusæ

(jelly fish) and the closely related Siphonophores, of which the beautiful Portuguese man-o-war is the most familiar representative. The class of worms is represented by many free-swimming species, but in the number of individuals it is far surpassed by the mollusca, chiefly represented by the squids, the pearly and paper nautilus, and the huge cuttlefish, and by the minute and delicately beautiful sea butterflies (Pteropods), which occur in vast schools in the polar seas. Often, too, in very considerable number are found the free-swimming larvae of Echinoderms, as also many worm larvae, which, like the former, pass their adult life upon the bottom. Every haul of the gauze net is certain to contain some representatives of the great class of Crustacea, often great numbers of species, as well as of individuals. In distribution these seem to be subject to pretty definite laws, and a careful study of the phenomena would be of great interest. There are found also certain Tunicates, a group interesting because many investigators believe that here we find the transition from the invertebrate ancestor to the higher plane of life of which man is at present the highest representative.

The vertebrates of the Plankton embrace the great group of fishes, and in addition the marine birds, the seals and walrus, and finally the cetaceans. In this connection, too, the enormous number of fish eggs floating at the surface of the ocean, as well as the transparent, newly-hatched fry must be mentioned. Prof. Hensen hopes to get an idea of the approximate number of fish of a given species in a certain area, computing the number of eggs and fry of that species within that area.

The phenomenon of marine phosphorescence is very widely known with admiration and wonder. Its cause is chiefly or solely bound up with organic life. The majority of pelagic animals display the phosphorescent light in different degrees. In some the entire living animal is brightly luminous, in other the light is limited to special organs. But much of the phosphorescence of the ocean appears to be caused by the fragments of dead organisms, and is connected with the presence of bacteria.

Since many chlorophyll bearing organisms are found at depths unpenetrated by sunlight, it has been suggested that the light necessary for their growth is furnished by the phosphorescent organisms.

The composition of the Plankton is exceedingly irregular, both in qualitative and in quantitative relations, its distribution in the ocean is also very irregular, both in time and in place. The variations occur near the shore as well as far out at sea. Very often the greater part of the mass of Plankton is made up of organisms belonging to a single group. Sometimes unicellular algae make up nearly the whole bulk, at another medusæ, siphonophores or ctenophores, indeed, almost any group of marine organisms may occur in such quantities as to compose more than one half of the total bulk of the Plankton, at that time and place. The fundamental causes of variation in the quantity and quality of the Plankton appears to be conditioned by time, climate, and currents.

*Temporal Differences*.—For a satisfactory determination of these more complete observations are needed. Reliable data can be furnished by the observations at the numerous marine laboratories and zoological stations now springing up in different parts of the world. The causes which underlie these yearly, monthly, daily, and hourly variations are manifold, in part meteorological, in part biological. They are comparable to the corresponding oscillations of the terrestrial fauna and flora, and depend on the one side upon climatic and meteorological conditions, and on the other upon the varying mode of life, particularly upon conditions of reproduction and development. Just as the annual development of most land plants is bound up with a definite time of year, as the time of budding and leafing, of blooming and fruiting, have in the "struggle for existence" become adapted to the meteorological conditions, the time of year, and other conditions of existence, so too the annual development of most marine animals is conditioned by definite habits, which have become fixed by heredity. The yearly variations may be compared to the good and bad fruit years. This yearly variation has been noted by many observers in case of many marine animals. Our attention is often called to an example of it in the unusual abundance or scarcity of the catch of certain food fishes.

Many marine animals, particularly certain medusæ, siphonophores, ctenophores, mollusca, and tunicates, are found at the

surface only periodically, in one or a few months of the year. This is probably dependent upon conditions of reproduction and development, as well as upon the temperature of the season. The daily variations are conditioned by the weather, and particularly by the wind and rain. A shower will very quickly reduce the specific gravity of the surface water and thus drive the surface-dwelling animals below. Many animals rise to the surface only at a definite time of day, some in the morning, others at noon, and yet others only towards evening.

*Climatic Difference*—Prof. Haeckel thinks that the quantity of the Plankton is very little dependent upon the climatic difference of the zones, but that the quality is greatly so, and indeed in this way, that the number of component species diminishes from the equator to the poles. These conditions, he believes, are directly referable to the influence of the sun, "the omnipotent creator," whose more direct rays bring about an acceleration in the processes which make up the cycle of life. As this is true of the terrestrial fauna and flora so it is true of the marine.

*Currentic Differences*—Conspicuous differences are also brought about by the numberless currents, great and small, by the little known deep sea oceanic currents as well as by the better known great surface currents, the Gulf Stream, the Falkland Stream, the Guinea Stream and others. These currents play a great rôle in the distribution of many forms of life. More local influences are exerted by the small currents whose causes are found in the climatic and geographical conditions of the adjacent coast. The relations of Plankton life to currents is little known, and needs investigation, but first a better knowledge of the currents themselves is necessary.

Almost every one who has seen the surface of the ocean in a calm has noticed the glassy areas of irregular shape. These are found on the high seas as well as in sheltered bays and harbours, and are of very special interest to the student of marine life. So far as made out they are extremely irregular in time and place of appearance, and the conditions governing them have not been carefully studied. They are in a measure influenced by winds and currents, by the ebb and flow of the tide. Here, into a limited space, are crowded great numbers of organic forms, this space is readily distinguished from the surrounding water in which there is comparatively little life. These phenomena have been noticed by seafaring men and have many different names in different countries.

A word in conclusion as to the bearing and importance of the Plankton in human economy in the near future. When Malthus promulgated his famous doctrine he failed to consider the final element which enters into the problem of human population, the human mind. The ingenuity of the human mind has brought about a decreased efficiency in the natural checks to undue increase, and thus an artificial increase in the food supply is rendered necessary for the crowding population. This food supply is now mainly derived from the cultivation of the land. A still further increase of population will necessitate a levy upon marine life. As soon as man to any great degree becomes a factor in the Plankton conditions by drawing from it large quantities of food, particularly in the form of mature animals, the equilibrium of oceanic life will be disturbed, and must be adjusted by artificial means. But further, a study of the phenomena of marine life shows that the water as well as the land, through cultivation, is capable of producing a greatly increased food supply for man. The necessity of cultivating the marine resources is even now apparent, and many governments have already begun to cope with the question by the establishment of commissions of fisheries. Of these commissions that of the United States stands in the front rank by virtue of its positive results. But in the near future individual attention must be turned to supplementing the terrestrial resources, the wheat fields, the cattle and sheep ranches, by an increasing utilization and development of the possibilities of marine farming, by fish propagation, by plantations of oysters, clams, quahaugs and scallops, by raising herds of lobsters and crabs. Improved breed of fish, of lobsters will result. The possibilities are well-nigh limitless, and by cultivation of the sea and sea bottom, as well as of the land, man will postpone indefinitely the fulfilment of the Malthusian prophecy.

But conditioning all advance in the possibilities of marine cultivation is the knowledge of the Plankton, of its distribution, and of the fundamental basis of marine life—the microscopic marine organisms in the ocean.

GEORGE W. FIELD

## OPTICAL PROJECTION<sup>1</sup>

THE intention of this lecture is to give a general survey of the subject of Optical Projection, which now takes its position in science, and to present examples of what may be done by this method. It would be difficult to determine which subject claims a first place. Some scientists say the microscope should have the preference, while others take a different view. For my own part, I think the microscope and polariscope stand foremost, or account of the facility with which these branches of science may be pursued for the benefit of a large number, without multiplying expensive apparatus, also because of the convenience in saving the eyes from undue strain. Indeed, to many persons, looking at objects in the table microscope is little short of a painful operation, and consequently the study of small objects becomes to them impossible. The projection method immediately brings the required relief.

For general instruction, projection methods are invaluable, such as, for instance, showing diagrams, photographs, and other slides, upon the screen, as well as for spectrum analysis. In fact, the subjects which can be illustrated by means of optical projection are innumerable, but time will allow me to present only a few examples, and I trust that, when I approach the end of my lecture, my view of the importance of this subject will be held in equal estimation by you.

Probably the only people in the world that benefit by the experience of their predecessors are those who pursue the study of science. They are free from the accusation of robbing the brains of other men, when they take up methods or apparatus already known and improve upon them or employ them for their own work. In such cases, however, it is always understood that honour should be given where honour is due, and accordingly I have no wish to represent to you any piece of apparatus as of my own devising, when in reality it belongs to another.

Few men have had a larger experience, and attained greater success in optical projection, than has Mr. Lewis Wright, who has embodied in his most recent forms of apparatus all that was good in designs existing until his time. I have, therefore, started from his models making such modifications as I thought to be desirable. Mr. Wright does not appear—if I may say so—to have had much experience with the electric arc light as a radiant, and I found, at a very early stage, that great difficulties had to be encountered when this light was used, chiefly because the radiant approaches more nearly to what theory requires. That which was easy with the lime-light became almost impossible with the arc lamp, and these difficulties had to be conquered.

Many scientific men are dissatisfied with the projection microscope, on the ground that very high magnification does not give that resolution and that sharpness which is found in the usual methods of observation. This want I fully admit. At the same time it is scarcely right to condemn a particular method because you try to apply it to an unsuitable purpose. Hundreds of thousands of subjects may be shown with the projection microscope with far greater profit to the student than was possible in the old way. The very fact that the professor can place his pointer upon any part of the picture on the screen is invaluable to the students. I shall, therefore, attempt to show you only a series of microscopical subjects suitable for projection, and shall not employ very high magnification.

In regard to some substances very high powers may be used with advantage, but much time would be lost in getting them into the field and focussing them upon the screen. These, consequently, I omit, so that a large number of subjects may be illustrated.

It is fair to state that most of the apparatus used to night has been constructed by Messrs. Newton, of Fleet street, and the luminous pointer by Messrs. Steward, of the Strand. The arc lamp is a Brockie's projector. Messrs. Baker, Watson, and others have also come to my assistance.

I will first show, on the screen, a picture of the lantern carrying its various apparatus, and then a few systems of lenses, which may be employed for the projection microscope, as well as a diagram of the microscope itself.

Sub-stage condensers and objectives are, as a rule, made to suit the table microscope. When projecting, by means of an objective alone, in consequence of the screen distance being very

<sup>1</sup> Friday evening discourse delivered by Sir David Salomons at the Royal Institution, on February 2d.

great—or, in other words, the microscope tube being exceedingly long as compared with the table instrument—the objective has to be approached very close to the slide, in fact, with the higher powers, closer than the cover-glass will allow. This close working distance renders necessary special sub stage condensers, and in many cases a special one is required for every screen distance with each objective. This requisite would seem to be a complete stumbling block to microscope projection work. With the lime light the difficulty does not enter in the same degree as with the arc light, and as we are now dealing with the latter, further reference need not be made to the oxy-hydrogen light. There are two ways of surmounting the difficulty, one by the use of plano concave lenses, introduced in such a way as to be equivalent to greatly lengthening the focus of the objective on the screen side, while it enables, as a consequence, the objective to be slightly further removed from the slide, *i.e.*, giving what is termed a greater working distance. The objection to this method is that, even when these plano-concave lenses are corrected, the result, though greatly improved, is not perfect. The second way, which is a perfect one, is that of introducing an eye-piece. In both these methods, that the best results may be obtained, the objective is made to occupy a position not very different from that which it would do if employed on the table microscope.

In the eye-piece method almost the exact conditions can be complied with for which the objective was made. I propose, therefore, to show the subjects by the eye-piece method. The only objectives which will be used are (1) Zeiss's 35 millimetre projection objective, with a sub stage condenser, 4 inches focal length placed a considerable distance from the slide, (2) Newton's 1 inch projection objective, the sub-stage condenser as in the first case, and (3) Zeiss's  $\frac{1}{2}$  inch achromatic objective, the sub stage condenser being Prof. Abbe's three-lens condenser with the front lens removed. In all three cases the eye pieces used are Zeiss Huyghens No. 2 and No. 3.

In each instance I will mention the magnification in diameters, as well as the number of times when reckoned by area, for the appreciation of those who estimate by area, and I will also give the size to which a penny postage stamp would be increased, supposing it to be made of India rubber, and stretchable to any extent in all directions. In presenting these figures I do not pretend that they are absolutely correct, but as they have been ascertained under conditions similar to those now existing the errors will not be very great.

In consequence of the field not being quite flat, and the sections having a certain thickness, although extremely thin in most cases, the whole of the object cannot be in focus upon the screen at the same time. By shifting the focussing screw slightly all parts may be brought into focus successively. So called greater depth of focus is obtained by using an increased working distance, and for projection work over correction for flatness can alone give a sharp picture all over with very considerable depth of focus, the difficulty of over-correction being that, unless extreme care is taken, certain forms of distortion may be introduced. By stopping down the objective greater flatness of field may be secured, but at the expense of light. There is thus a choice of difficulties, and the least one should be taken.

Turning now to the polariscope. Polarized light teaches us a great deal concerning the structure of matter, it is also a means of confirming the undulatory theory of light. This subject is so large that no attempt can be made to give even a general idea of the field it covers, and the experiments, which will be shown in the polariscope, may be taken simply as a few illustrations of the subject and nothing more, but they will, at any rate, be suggestive of the large field to which this method of analysis can be applied. A vast amount of mathematical proof can be illustrated graphically by various experiments with polarized light. I will show on the screen a diagram of the polariscope. (Shown.)

With reference to showing the spectrum. The method of projecting a spectrum, I think, is new, as I have not seen it described anywhere. It gives practically a direct spectrum with an ordinary prism, without turning the lantern round to an angle with the screen, and here is a diagram of the method.

The details of the apparatus, as well as those of the methods of working, I have modified in almost every instance, for five reasons:—(1) That more certain results may be ensured, (2) that rapidity may be obtained; (3) that only one operator may be needed, (4) that, as far as possible, all parts of the apparatus may be interchangeable; and (5) that loose screws and pieces may be dispensed with.

There were then shown by projection a number of slides illustrating various microscopic optical systems, and a number of microscopic slides, followed by a series of general polariscopic projections, some of them to illustrate the strains existing in many forms of matter, also a spectrum by a carbon disulphide prism, in conjunction with a reflecting prism and with a mirror, which, apart from any other result, demonstrates that the loss of light with a reflecting prism is less than with an ordinary glass mirror. Slides and other projections were also thrown upon the screen.

The details are as follows—

*The Microscope*—Screen distance, 21 feet. First 35 millimetres Zeiss projection objective, 4 inch sub-stage condenser, Zeiss Huyghens eye piece 2, 500 diameters = 250,000 times = penny stamp stretched to cover about 147 square yards. Subjects shown: proboscis of blowfly, permanent molar displacing milk-tooth (kitten), human scalp, vertical, human scalp, surface, fossil ammonites and belemnite. Second, 1 inch Newton's projection objective, 4 inch sub-stage condenser, Zeiss Huyghens's eye-piece 2, 1,000 diameters = 1,000,000 times = stamp stretched to about 588 square yards. Objects shown: proboscis of blowfly, foot of a caterpillar, section of human skin, showing the sweat ducts, phylloxera vastatrix of the vine. Third, 1-inch Newton's projection objective, 4-inch sub stage condenser, Zeiss Huyghens eye-piece 3, 1,300 diameters = 1,690,000 times = stamp stretched to about one fifth of an acre. Slides shown: proboscis of blow-fly, wings of bee (showing hooklets and ridge), sting of bee (showing the two stings, sheath, and poison sack), sting of wasp (showing same as last slide), eye of beetle (showing the facets). Fourth,  $\frac{1}{2}$  inch Zeiss's achromatic objective, Abbe's 3-lens sub stage condenser, with top lens removed, Zeiss Huyghens eye piece 3, 4,500 diameters = 20,250,000 times = stamp extended to nearly 2½ acres. Slides shown: proboscis of blow fly, hair of reindeer (showing cell structure), hair of Indian bat (showing the peculiar funnel-like structure), sting of bee (showing the barbs), foot of spider, stage of the micrometer (the closest lines ruled to thousandth of an inch, which measure  $\frac{1}{4}$  inches apart under this magnification), a wave length  $\frac{1}{40000}$  inch, therefore, on screen measures about  $\frac{1}{4}$  inch.

*The Polariscope*—Shown with parallel light: plain glass, glass under pressure, chilled glass (round, oval, and waved peripheries), Prince Rupert's drop (broken in the field), horn, selenites (over-lapped), butterfly (selenite), bunch of grapes (selenite), bi-quartz, with  $\frac{1}{2}$ -wave plate (the  $\frac{1}{4}$  wave plate in this experiment produces the same effect upon the bi-quartz as if a column, 20 centimetres long, of a 7½ per cent solution of cane sugar were placed between the polarizing nicol and the bi-quartz. The analyser has to be rotated about 10°), a piece of sapphire to show asterism. Shown with convergent light, hemitrope (cut in a plane, not at right angles to the axis), topaz, grape sugar (diabetic), cane sugar, quartz, superimposed right and left-handed quartz (spirals), calcite and phenocryst superposed (showing transition from negative to positive passing through the apophyllite stage).

*The Solidscope*—New form of apparatus for showing solids, and consisting of two reflecting prisms and suitable projecting lenses. With this instrument were shown—Barton's balloon, the works of a watch, a coin.

*Spectrum Analysis*—Spectrum thrown by means of a disulphide prism combined with a reflecting prism, the result being that a good spectrum is thrown upon the screen direct without turning the lantern. There were shown—The spectrum, absorption bands of chlorophyll, &c., effects produced by passing the light through coloured gelatine films.

*Projection of Slides*—Decomposition of water; expansion of a wire by means of heat; combination of colours to form white light, various diagrams, coloured photographs of a workshop, &c. As an extra experiment there was shown, in the polariscope, with a convergent light, Mitscherlich's experiment (illustrating the changes which take place in a selenite under the influence of heat).

There are but few who would disagree with me in the opinion that the microscopic world, as regards its design and its molecular structure, is quite as wonderful as the great works around us seen with the unaided eye. A magnifying glass of low power opens up a world far larger than that which we are accustomed to see. At the present time, even with the most perfect apparatus that exist, only a small portion of the universe is known to us.

Scientific study should be pursued by all in a greater or less degree. It teaches more important lessons than the most impressive discourse ever preached. During the investigation of what is generally termed the invisible world, men should at time pause to reflect, and ask themselves such questions as these: What is the meaning of, and to what end is, creation? Is it all mere chance? Were such wonderful designs and properties created at the beginning? Was there in matter at the beginning an inherent, or implanted, power of development? Simple as these questions may seem, man in the flesh will never be able to find the true answers. The extraordinary design and structure which have existed in the unseen world for millions of years, or possibly in all past time, and even at the present day known to so few, demonstrate at least that the great Power has bestowed the same care upon what appear to us the most insignificant portions of creation, as upon what we think are the greatest works in the universe. These silent sermons must surely influence the mind, and set it thinking of the supernatural and of our duties during life.

It may now with truth be said that science gives us means, such as never before existed, of appreciating the greatness of the Supreme Spirit, by enabling us to read fresh chapters in the book of nature.

### UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Prof. Darwin has been appointed to represent the University at the approaching tercentenary of Galileo's appointment to a chair in the University of Padua. The celebration will take place in Padua at the beginning of December.

Prof. Green, of Oxford, is appointed an Elector to the Harkness University Scholarship in Geology in the place of the late Mr. T. Roberts, assistant to the Woodwardian Professor.

The discussion in the Senate of the proposal to found a mechanical sciences tripos for engineering students was unexpectedly favourable, in marked contrast to the reception accorded to former schemes. Prof. Ewing is to be congratulated on the skill with which the new plan has been framed, and the success with which he has met and conciliated the original opposition of the more mathematical members of the Senate. The grants for the approval of the plan have been sanctioned by the Council, and it is not likely that they will now be opposed. Some fifteen students are already at work in the engineering laboratory in preparation for the new tripos, which bids fair to take a good place among the honours schools, and cannot fail to stimulate the growth of the engineering department under its present energetic head.

DUBLIN.—At the meeting of Council of the Royal College of Science, Dublin, held on the 5th inst., a letter was read from H. M. Commissioners for the Exhibition of 1881, announcing that they had been pleased to place at the disposal of the College a science scholarship of the annual value of £150 for the year 1893. These scholarships are specially instituted for the encouragement of scientific research and are tenable for two years, and one of them has already been nominated to by the Council of the College for the year 1891-92.

### SCIENTIFIC SERIALS

*American Journal of Science*, October.—On a colour system, by O. N. Rood.—An otterite-bearing phase of a metamorphic conglomerate in the Green Mountains, by C. L. Whittle.—The age-coating in incandescent lamps, by E. L. Nichols. The diminution of efficiency in incandescent lamps is due to three causes, viz., loss of vacuum, increase of resistance due to the disintegration of the filament, and finally the deposition of disintegrated carbon upon the inner surface of the lamp-bulb. This deposition gives rise to what is called the age-coating. It appears that the rate of deposit of the coating in incandescent lamp-bulbs is greatest in the early part of the life of the lamp. For example, in the case of a lamp which lasted 800 hours, more than half the coating was deposited during the first 200 hours. The loss of brightness due to the absorbing power of the age-coating is a variable part of the total loss, being greatest in lamps of high initial efficiency. The coating does not appreciably modify the character of the light transmitted, as shown by a series of photo-spectroscopic measurements. The distribution of the coating within the bulb is nearly uniform. No marked differ-

ence between treated and untreated filaments appears to exist as regards the coating produced from them. It has been pointed out, however, that in the case of lamps exhausted without the aid of mercury the age-coating is scarcely perceptible.—Mica-peridotite from Kentucky, by J. S. Diller.—Glaciation in the Finger Lake region of New York, by D. F. Lincoln.—Certain points in the interaction of potassium permanganate and sulphuric acid, by F. A. Gooch and E. W. Danner. When these two bodies are brought into solution together there is developed a tendency towards reduction on the part of the permanganate, which is the greater as the strength of the acid is increased, as the temperature is raised, and as the duration of the action is extended. At first, the oxygen lost to the permanganate is liberated, whereas in the later stages manganese is precipitated in the form of a higher oxide or retained in solution in the form of a higher sulphate.—Crystallography of the cesium mercuric halides, by S. L. Penfield.—Silver hemisulphate, by M. C. Lea.—Restorations of Claosaurus and Ceratosaurus, by O. C. Marsh.—Restoration of *Mastodon Americanus* (Cuvier), by the same.

THE number of the *Nuovo Giornale Botanico Italiano* for October is entirely occupied by the continuation of Sig. Nicotia's Statistics of the Flora of Sicily.

*American Journal of Mathematics*, vol. xiv, No. 3 (Baltimore, the John Hopkins Press, 1892).—The title of Prof. Cayley's communication, "Corrected Seminomial tables for the Weights 11 and 12" (pp. 195-200) explains itself. It contains a better form of tables, which were given in a previous volume (vii, pp. 59-73). Weierstrass, in his memoir "Zur Funktionenlehre," called attention to certain functions, which offer special singularities. "Au lieu de présenter un nombre fini ou infini de points singuliers essentiels isolés elles offrent des lignes singulières essentielles ou même des espaces lacunaires à l'intérieur desquels elles cessent d'exister."—By request of Mr. Hermit, M. H. Poincaré discusses the subject in an article "Sur les fonctions à espaces lacunaires" (pp. 201-221).—J. C. Field, writes on "Transformation of a System of Independent Variables" (pp. 230-236).—Mansfield Merriman discusses "The deduction of final formulas for the Algebraic Solution of the Quartic Equation" (pp. 237-245), and I. S. Hulburt in remarks on "A class of new theorems on the number and arrangement of the real branches of plane Algebraic Curves" (pp. 246-250), follows up recent work, in the same direction, by Messrs. Harnack and Hilbert.—"The Symbolic notation of Aronhold and Clebsch" (pp. 251-261) has for its object the exposition of this notation, "so well adapted to the expression of functional invariants," in an English form. The same writer, W. F. Osgood, also contributes a note on "the System of two simultaneous Ternary Quadratic forms" (pp. 262-273). This, likewise, is a simplification for the benefit of English readers. It contains an account of Gordon's method, and employs the notation of the preceding article.—H. S. White communicates notes "on generating systems of Ternary and Quaternary Linear transformations" (pp. 274-282), and "a Symbolic demonstration of Hilbert's method for deriving Invariants and Covariants of given Ternary forms" (pp. 283-290). This latter paper also uses the symbolic notation of Aronhold and Clebsch in a simplified statement of recent results developed in Hilbert's notable paper "Ueber die Theorie der Algebraischen Formen" (Math. Aca., vol. 36, pp. 524-6). The only paper, in the present number, which was read before the New York Mathematical Society is one by the President, Emory McClintock, "On the Computation of Covariants by Transvection" (pp. 222-229).

### SOCIETIES AND ACADEMIES

#### PARIS

Academy of Sciences, October 17.—M. Duchartre in the chair.—On Mr. Barnard's discovery of the fifth satellite of Jupiter, by M. F. Tisserand.—On the application of certain methods of successive approximation to ordinary differential equations, by M. Emile Picard.—On a reaction alleged to be peculiar to spermine, by M. Duclaux.—Observations of three new small planets discovered at the Nice observatory by means of photography, by M. Charlois; report by M. Perrotin (see *Astronomical Column*).—On the coexistence of dielectric power and electrolytic conductivity, by M. E. Bouty. A vindication of priority.—On the polarization of light of various colours by the atmosphere, by M. N. Piltchikoff. There is a well marked difference between the intensity of polarization of blue light and that of red in the atmosphere. The intensities are measured by

means of a Cornu photo polarimeter. The eye-end of this instrument is covered with a cobalt glass, the quantity of polarized light from the chosen point in the sky is measured, the blue glass replaced by a ruby glass, and the determination repeated for the latter. Generally, the intensity of polarization for blue light is sensibly greater than that of the red. This is not favourable to Lallemand's theory of the blue colour of the sky as a phenomenon of fluorescence. The difference of polarization is, however, not constant, but depends upon the direction of the wind. A series of observations made at Kharkoff between April and September, 1892, show a maximum difference with a south easterly wind, diminishing symmetrically on both sides, and even becoming negative at W N W. The amount of polarization of the blue shows the opposite distribution, so that when the polarization of the atmosphere rises or falls, the effect is greater in the less refrangible radiations than in the others. There is also a notable relation between polarization and atmospheric moisture. The S.E. brings the greatest amount of precipitation, the northerly winds the least. It is also probable that dust and dry fogs exert a considerable influence, as shown by the circumstance that the greatest differences have been obtained in high winds, when the whole town was covered with dust. On a new way of preparing acetylene, by M. I. Maquenne (see Notes).—On the analysis of mixtures of ammonia and methylamines, by M. H. Quantin.—On the nervous tissues of some invertebrates, by M. A. B. Griffiths.—Examination of some rocks collected by Prince Henry of Orléans on the lower Black River in Tonkin, by M. Stanislas Meunier.—Note on the miocene formations of western Algeria, by M. Jules Welsch. The miocene formations occur in normal succession near Hamman Riva, where they rest on the Cretaceous. It appears certain that the last upheaval of the Atlas did not take place at the end of the Helvetic epoch (middle miocene), as hitherto believed. It was post Tortonian, and took place at the end of the upper miocene. For the formations of Gontas, Ben Chicao, Mascara, &c., are Tortonian, they are within the block of the Atlas Mountains, and have been lifted to heights of 800, 1000, and even 1700 metres. This result tends to confirm the general idea worked out within the last few years that the zones of folding are nearer the equator in proportion as they are more recent.

## AMSTERDAM

Royal Academy of Sciences, September 24, Prof. Van de Sande Bakhuyzen in the chair.—Mr. H. A. Lorentz dealt with the reflection of light by moving bodies. In a former paper ("Arch. neerlandaises," t. xxv, p. 363) the author considered the propagation of light through a ponderable dielectric which has a movement of translation, but leaves at rest the enclosed ether. The equations then arrived at may be written in the form—

$$\text{div } D = 0, \quad \text{div } H = 0, \\ \text{curl } E = -II, \quad \text{curl } \left[ H + \frac{1}{v} \text{vect } (E\beta) \right] 4\pi D,$$

$$4\pi V^2 D = n^2 E + \text{vect } (H\beta),$$

the vectors  $H$ ,  $D$ ,  $E$ , and  $\beta$  representing the magnetic force, the dielectric displacement, the electric force, and the velocity of the ponderable matter. The signs "div" and "curl" have the same meaning as in Heaviside's formulæ (*Phil. Mag.*, 5th ser. vol. xxii, p. 118), and  $\text{Vect } (E\beta)$  indicates the vector product. Finally,  $V$  is the velocity of light in vacuum, and  $n$  the index of refraction. At the boundary of two media, possessing a common translation, there will be continuity of the normal components of  $D$  and  $H$ , and of the tangential components of  $E$  and  $\left[ H + \frac{1}{v} \text{vect } (E\beta) \right]$ . If  $i$  and  $r$  are the angles of incidence and refraction for the relative rays ("Arch. neerlandaises," t. 21, pp. 129–134), Fresnel's expressions for the amplitude of the reflected ray—

$$\frac{\sin(i-r)}{\sin(i+r)} \quad \text{and} \quad \frac{tg(i-r)}{tg(i+r)}$$

have to be multiplied by

$$1 - \frac{2\beta_1 \cos i}{V n_1},$$

where  $n_1$  relates to the first medium, and  $\beta_1$  is the velocity, in the direction of the normal, with which the reflecting surface recedes. This result may be shown to be consistent with the conservation of energy, provided that the pressure exerted, according to Maxwell, by the vibratory motion, be taken into account.—M. van Bemmelen made a second communication on

the existence of the crystalline hydrate of  $\text{Fe}_2\text{O}_3$ . He obtained the ferrite of sodium ( $\text{Fe}_2\text{O}_3 \cdot \text{Na}_2\text{O}$ ) in different crystal forms. Under certain circumstances this form was a hexagonal plate. These crystals could be metamorphosed by the action of water in the hydrate of  $\text{Fe}_2\text{O}_3$ , without loss of their optical properties.

## BOOKS, PAMPHLETS, and SERIALS RECEIVED

BOOKS.—The Student's Hand book of Physical Geology. A. J. Jukes-Browne, 2nd Edition (Bell). The Beauties of Nature. Sir John Lubbock (Macmillan).—Notes on Qualitative Chemical Analysis. P. L. N. Nayudu (Madras, Chetty).—Amherst Trees. J. E. Humphrey (Amherst, Mass., Carpenter).—Magnetical and Meteorological Observations made at the Government Observatory, Bombay, 1890 (Bombay).—Explosives and their Power. M. Berthelot, translated by C. N. Hake and W. Macnab (Murray).—Domestic Electric Lighting, treated from the Consumer's Point of View. F. C. de Segundo (Alahuter).—Introduction to Physiological Psychology. Dr. I. Ziehen, translated by C. van Liew and Dr. O. Beyer (Sonnenchein).—Notes by a Naturalist. H. N. Moseley. New Edition (Murray).—The Science and Practice of Lighting. W. H. Y. Webster (W. Knight).—Commercial Organic Analysis, vol. 1, Part 2, and Edition A. H. Allen (Churchill).—Comité International des Poids et Mesures. Procès Verbaux des Séances de 1891 (Paris, Gauthier Villars).—The Reliquary, vol. 6, New Series (Hemrose).—Vergleichende Morphologie der Pflanze. Dr. F. v. Tavel (Jena, Fischer).—Beiträge zur Biologie und Anatomie der Linsen. Erster Theil, Beiträge zur Biologie der Linsen. Dr. H. Schenck (Jena, Fischer).—Dissections Illustrated, Part 1, the Upper Limb. C. J. Brindley (Whitaker).—Science Instruments (Newcastle-on-Tyne, Brady and Martin).—Treatise on Thermodynamics. P. Alexander (Longmans).—Vegetable Wasps and Plant Worms. Dr. M. C. Cooke (S. P. C. K.). Text book of Petrology. Dr. F. H. Hatch, 2nd Edition (Sonnenchein).—Meteorological Service Report, 1888. C. Carriacul (Ottawa, Dawson).

PAMPHLETS.—The Inaugural Robert Boyle Lecture. Sir H. W. Acland (Frowde).—Astronomical Observations made at the University Observatory, Oxford, No. 4, Researches in Stellar Parallax by the Aid of Photography, Part 2. Prof. Pritchard (Oxford, Clarendon Press).

SERIALS.—Records of the Australian Museum, vol. 2, Nos. 2 and 3 (Sydney).—Journal of State Medicine, vol. 1, No. 2 (Griffin).—Journal of the Chemical Society, October (Gurney and Jackson).—Zeitschrift für wissenschaftliche Zoologie, 51. Band, 3. Heft (Williams and Norgate).—Journal of the Royal Microscopical Society, October (Williams and Norgate).—Journal of Anatomy and Physiology, vol. 27, New Series, vol. 7, Part 1 (Griffin).

- ABASTOU IAN, a New Observatory at, 133  
 Abbadie (M. d'), on the Variations in the Intensity of Terrestrial Gravitation, 384  
 Abbe (Prof. C.), Atmospheric Electricity, Earth Currents and Terrestrial Magnetism, 261  
 Abbott's (Dr. W. L.) Collections of African Mammals, F. W. True, 39  
 Abbott (W. J. L.), Walrus in the Thames Valley, 132  
 Abney (Captain W. de W., F.R.S.), Sensitiveness of the Eye to Light and Colour, 539  
 Abnormality in the Veins of the Rabbit, on an, Prof. W. N. Parker, 270  
 Absorption of our Atmosphere, Photographic, Prof. Schaeberle, 304  
 Abyssinia, Proposed Expedition of Mr. and Mrs. Theodore Bent to, 115  
 Academy, French, Science Prizes, 232  
 Academy of Sciences, Turin Royal, the Bressa Prizes, 233  
 Acoustics, on Plane and Spherical Sound-Waves of Finite Amplitude, Dr. C. V. Burton, 500  
 Addenbrooke (Mr.), Diffusion of Light, 191  
 Aeronautics Meteorological Balloon Ascent at Berlin, A. I. Roth, 45, Dirigible Balloon in Construction at Chalais Meudon, 112, Exploration of the Higher Regions of the Atmosphere by Means of Free Balloons provided with Automatic Recorders, Gustave Hermite, 110, the First Aerial Voyage across the English Channel, R. de C. Ward, 143, the Longest Balloon Ascent on Record, Maurice Mallet, 182  
 Africa Marine Shells of South Africa, G. B. Sowderby, 27, the Ferns of South Africa, Thos. R. Sim, J. G. Baker, F.R.S., 291, Dromedaries in German South West Africa, Captain von François, 38, New Harbour found in German South West, 452, Dr. W. L. Abbott's Collection of African Mammals, F. W. True, 39, Mr. D. J. Rankin's Zambesi Journey, 64, Kettler's Afrikanische Nachrichten, 115, Captain H. L. Gallwey's Travels in Benin Country, 134, E. Wilkinson's Journey in Kalahari Desert, 134, M. Alexandre Delcommune's Lomami Expedition, 209, the Uganda Commission, 210, Proposed Exploration of Africa by Telegraph, Cecil Rhodes, 210, the Honjo, a Cannibal Tribe, M. Dybowski, 257, Territorial Nomenclature, 282, the Stanley Falls District of the Congo, M. Page, 282, African Nomenclature, 304, Stoppage of M. Mizon's Adamawa Expedition, 304, Aston Chanler's Expedition to Lake Rudolf, 327, the Soil of Sakalava Plain, Madagascar, Emile Gautier, 327, the Frontier Delimitation between British South Africa Company's Territory and Portuguese Possessions, Major Leverton, 327, Death of R. H. Nelson, 353, Dr. Baumann's Journeys in the Nile-Sources Region, 377, the Orthography of African Place Names, 400, Two Akka Girls brought to Germany by Dr. Stuhlmann, 470, the Katanga Company's Expeditions, 474, French Exploration towards Lake Chad, 519, Arrival of Mr. and Mrs. Theodore Bent at Adowa, 519, at Aksum, 547, the Partition of Africa, J. Scott Kettle, 580, Return of the Delcommune Expedition, 590  
 Afterglow, the, Serebo E. Bishop, 102, Prof. Grenville A. J. Cole, 127  
 Afterglows and Bishop's Ring, the, T. W. Backhouse, 582  
 Agassiz (Prof. A.), Observations in the West Indies, 608  
 Age, the Earth's, Bernard Hobson, Dr. Alfred Russel Wallace, 175, 226, Clarence King, 285  
 Ages, Ancient Ice, J. Lomas, 227  
 Aggressive Mimicry, the *Volucella* as Examples of, Edward B. Poulton, F.R.S., 28  
 Aggressive Mimicry, the Alleged, of *Volucella*, William Bateson, 77  
 Agriculture the South Australian Rust in Wheat Conference, 86, the Plague of Field Voles in Scotland, 155, the Plague of Field Mice in Thessaly and Scotland, 396, Agriculture in the United States, Experiment Stations, A. Warrington, F.R.S., 157; Investigations in Soils, 157, Influence of Manure on Development of Roots, M. Dehérain, 280, Journal of the Royal Agricultural Society of England, 285, Field Experiments on the Fixation of Free Nitrogen, James Mason, 285, Yew Poisoning, E. P. Squarey, Charles Whitehead, W. Carruthers, F.R.S., and Dr. Munro, 285, Proposed Investigation of Chemical Composition of Soil in Cape Colony, 301, a Text-book of Tropical Agriculture, H. A. Alford Nicholls, 313, the Florida Phosphate Beds, F. N. Lupton, 325, the New York State Pecuniary Contribution to Agriculture, 349, Wood Ashes as a Medicine for Farm Animals, J. M. Stahl, 397, Proposed Commemoration of the Jubilee of Sir John Lawes' Rothamsted Experiments, 448, Ornithology in Relation to Agriculture and Horticulture, John Watson, 533, Manual of Dairy Work, Prof. James Muir, Walter Thorp, 555, Agricultural Chemistry, the Food of Plants, A. P. Laurie, 556  
 Aids to Experimental Science, Andrew Gray, 173  
 Aignan (M. A.), Action of Temperature upon the Rotatory Power of Liquids, 576  
 Ainu, Yezo and the, Prof. J. Milne, F.R.S., 330, A II Savage Landor, 330  
 Air pumps, Automatic Mercurial, Dr. August Raps, 369  
 Aitken (John), on the Particles in Fogs and Clouds, Akka Girls, Two, brought to Germany by Dr. Stuhlmann, 470  
 Alabama, Great Meteor in, 86  
 Alcohol Solutions, Temperature of Maximum Density of, L. de Coppet, 48  
*Aleynaria Stolonifera*, Revision of Genera of, Dr. Hickson, 215  
 Alexander (Peter), Treatise on Thermodynamics, 388  
 Algebra Principles of the Algebra of Vectors, A. Macfarlane, 3, the Algebra of Co-planar Vectors and Trigonometry, R. Baldwin Hayward, F.R.S., 266, Quaternions and the Algebra of Vectors, Prof. J. Willard Gibbs, 463, Algebra for Beginners, H. S. Hall and S. R. Knight, 28, the Theory of Substitutions and its Applications to Algebra, Dr. Eugen Netto, 338, a new Algebra, T. B. Sprague, 527  
 Alkali Metals, the Colours of the, G. S. Newth, 55, Wm. L. Dudley, 175  
 Allen (Elgar), Anatomy of Larva of *Palamonomes varians*, 237, on the Minute Structure of the Gills of *Palamonomes varians*, 261  
 Allen (F. J.), Dust Photographs, 341  
 Allen (Grant), Science in Arcady, 173  
 Alligators' Nest, the, S. Devenish, 587  
 Alloys, on Iron, 58  
 Alloys Research Committee, Second Report of the, Prof. W. C. Roberts-Austen, F.R.S., 617  
 Almanac, the Nautical, for 1896, 326  
 Alpes Françaises, les, Albert Falsan, 76  
 Alpine Flowers, on the Cause of Bright Colours of, Dr. J. Joly, F.R.S., 431  
 Alpine Lakes, the Glacier Theory of, Dr. Alfred Russel Wallace, 437  
 Alsace Lorraine, Statistics of Wine growing in, 614  
 Aluminium Slate Pencils, 131  
 Amygdal (E. H.) the Laws of Compressibility of Liquids, 48, Laws of Dilatation of Gases under Constant Pressure, 96

- Ornithology, a Fork tailed Petrel, Newman Nerve, 31, the Food of Humming birds, Dr Morris Gibbs, 63, Assumption of the Male Plumage by a Pea-hen, G N Douglas, 71, Corncrake Caught in Wales, December 8, 1892, 157, the Migration of Birds, an Attempt to Reduce Avian Season Flight to Law, Charles Dixon, 169, Study of the Form of Eggs, Dr Nicolsky, 253, Death and Obituary Notice of Rev F O Morris, 372, the Flight-Speed of Wild Ducks, H L Clark, 374, the Preservation of the Native Birds of New Zealand, 394, Death and Obituary Notice of Victor Aimé Leon Olphe Galliard, 395, the Flight of Birds, Herbert Withington, 414, Formation of a Cage Bird Club, 495, Ornithology in Relation to Agriculture and Horticulture, John Watson, 533, the Protection of the Osprey in Scotland, 42
- Osborn (Prof Henry F.), Protocerus, the New Artiodactyle, 321, Attonyx, a Clawed Artiodactyle, 610
- Osmium, Chemistry of, A E Tutton, 400
- Osmium, Metallic, M Joly and Vèges, 497
- Osmotic Pressure, J W Rodgers, 103, Prof Spencer Pickering, F R S, 175
- Osprey in Scotland, the Protection of the, 612
- Ostwald's Klassiker der Exakten Wissenschaften, Nos 31-37, 149, 38-40, 245
- Oudemans (Dr A C), the Great Sea Serpent, 506
- Owen (Sir Richard), Obituary Notice of, 181, the Proposed Memorial to, 232, 252, 307
- Oxford, Medical Education at, Lord Salisbury, 449
- Oxford Medical Society, Inaugural Address by Sir James Paget, 60
- Oxford University Junior Scientific Club, 95, 119, 167, 359, 431, 502
- Oxford University Museum, Catalogue of Eastern and Australian *Lepidoptera heterocera* in the Collection of the, Col C Swinhoe, 53
- Oxley (Rev W H), Travelling of Roots, 414
- Oxygen for Limelight, T C Hepworth, 176
- Oxygen, Liquid, Use of Total Reflection to Determine Light-Refraction of, Herren Olzowski and Witkowski, 614
- Oyster Culture, on the Attempt at, in the Roscoff Laboratory, M de Lacaze Duthiers, 456
- Oysters, Observations on, Prof R C Schledt, 375
- Ozone, D A Van Bastelaer's Observations on, 373
- Ozone, W G Black, 390
- Pacific Slope, Grasses of the, including Alaska and the adjacent Islands, Dr Geo Vasey, 173
- Paddington Railway, Clapham Junction and, 515
- Paderborn, Shower of Pond Mussels at, 278
- Padua, Galileo Galilei and the Approaching Celebration at, Prof Antonio Favaro, 82, 180
- Pag (M), the Stanley Falls District of the Congo, 282
- Paget (Sir George E., K C B, F R S), Some Lecture, by, 485
- Paget (Sir James) Inaugural Address to Oxford Medical Society, 60
- Paleolithic or Unground Stage of the Implement-makers' Art, On the Rude Stone Implements of the Tasmanians, showing them to belong to the, Dr Tylor, 527
- Palaemonetes Varians*, Anatomy of Larva of, F J Allen, 237
- Palaeontology, Discovery of Ureus Arctos in the Malta Pleistocene, J H Cooke, 62, Relics found in Yorkshire Caves, Rev Edward Jones, 112, Walrus in the Thames Valley, W J L Abbott, 132, Some New Reptiles from the Egin Sandstone, E T Newton, 189, Death of Dr D Stur, 206, Protocerus, the New Artiodactyle, Prof Henry F Osborne, 321, Restoration of Anchisaurus Colurus, Prof O C Marsh, 349, a Catalogue of British Jurassic Gastropoda, W H Huddleston, F R S, and Edward Wilson H Woods, 363, Johns Hopkins University Palaeontological Collections, 471, Fossil Fauna of the Black Sea, T J van Beneden, 544, Attonyx—a Clawed Artiodactyle, Prof Henry F Osborn, 610, Palaeontological Discovery in Australia, Prof Alfred Newton, F R S, 606
- Paleozoic Ice Age, a, W T Blanford, F R S, 101, 152, Henry F Blanford, F R S, 101
- Palestine, Geology of, Prof Edward Hall, F R S, 166
- Palmberg (Dr Albert), a Treatise on Public Health, Dr H Brock, 507
- Palmer (Mr), a Lilac Colour produced from Extract of Chestnut 132
- Papasogli, Colorimeter for Comparing Intensity of Colour in Solution, 131
- Papuans, the Native, T H Hatton Richards, 590
- Parallax of  $\beta$  Cygni, Harold Jacoby, 399
- Parallaxes of  $\mu$  and  $\theta$  Cassiopeiae, Harold Jacoby, 5
- Parasitism of *Volucella*, W E Hart, 78
- Parker (J), Carnot's Principle applied to Animal and Vegetable Life, 95
- Parker (Prof T Jeffrey, F R S), on the Cranial Osteology, Classification and Phylogeny of the *Dinornithidae*, 431
- Parker (Prof W N), on an Abnormality in the Veins of the Rabbit, 270
- Paris Academy of Sciences, 23, 47, 71, 96, 119, 143, 167, 192, 215, 239, 263, 287, 311, 335, 360, 384, 408, 431, 456, 479, 503, 527, 551, 576, 599, 623, Prize List for 1892, 215
- Paris Observatory in 1892, M Tisserand, 546
- Paris, the Question of the Purity of Ice Consumed in, 614
- Parry (John), on the American Iron Trade and its Progress during sixteen years, Sir Lowthian Bell, F R S, 195
- Pasquale (Dr B), the "Mal Nero" Vine Disease, 130
- Pasquale (Cav G A), Death of, 421
- Passy (Jacques), Analysis of Complex Odours, 48
- Pasteur (M), Proposed Testimonial to, 37
- Pasteur's (M), Seventieth Birthday, 204
- Patagonia, Idle Days in, W H Hudson, Dr Alf Russel Wallace, 483
- Pathology, the Croonian Lecture, 487, on the Histology of the Blood of Rabbits which have been rendered Immune to Anthrax, Lim Boon Keng, 502
- Peal (S E), Lunar "Volcanoes" and Lava Lakes, 486
- Pearcey (F G), Foraminifer or Sponge? 390
- Pearry (Lieut), Proposed Arctic Expedition of, 133, 452
- Pekelharing (Mr), the Peptone of Kuhne, 624
- Peloponnes Der, Versuch einer Landeskunde auf Geologischer Grundlage, Dr Alfred Philippson, 6
- Pencils, Slate, Aluminium, 131
- Penck's (Prof), Scheme for a Map of the World on a uniform scale, 426
- Perfume Industry, Odorographia, a Natural History of Raw Materials and Drugs used in the, J Ch Sawyer, 52
- Peripatus Egg, the Hatching of a, Arthur Dendy, 508
- Perkin (W H, sen), Magnetic Rotation of Sulphuric and Nitric Acids, 165
- Perigal (Mr Henry), Complimentary Dinner to, 585
- Perigal Family, Longevity of the, Dr C T Williams, 585
- Perry (G H), Interaction of Iodine and Potassium Chlorate, 165
- Perry (Prof J, F R S) on the differential equation of Electric Flow, 574, on the Viscosity of Liquids, 575
- Persei, Motion of  $\beta$ , 115
- Persei, Relative Position of Stars in Cluster  $\chi$ , Sir Robert Ball and Arthur Rambaut, 376

- Persei, the large Nebula near  $\xi$  (N G C. 1499), Dr Scheiner, 546
- Perseids, Observations of, 88
- Perthshire Society of Natural Science, Dr F. B. Waite's Collection of Lepidoptera presented to, 206
- Peru (Southern) Indications of a Rainy Period in, A. E. Douglass, 38
- Petrel, a Fork tailed, Newman Neave, 31
- Petrie (Prof. W. Flinders), appointed to Chair of Egyptology at University College, London, 111, First Lecture on Egyptology, 278, Ancient Egypt, 301
- Pflanzeneben, Anton Kerner von Marilaun 605
- Phenological Observations for 1892, Report on the, E. Mawley, 430
- Phœnician Tombs at Malta, Depredations among the recently-discovered, 396
- Philippson (Dr. Alfred) *Der Peloponnes, Versuch einer Landeskunde auf Geologischer Grundlage*, 6
- Phosphate Beds, The Florida, I. N. Lupton, 125
- Phosphorescence a new Luminous Fungus from India, 157
- Phosphorescence in Centipedes, R. I. Pocock, 545
- Photography *Traité Encyclopédique de Photographie*, Charles Fabre, 6, the Photography of an Image by Reflection, Frederick J. Smith, 10, Photographic Dry Plates, Arthur P. Brown, 11, Coloured Photographs of the Spectrum, G. Lippmann, 23, American Opinion of Photography in England, Xanthus Smith, 86, a Manual of Photography, A. B. Bowers, 98, Conditions of Production of Lippmann's Coloured Photographs, G. Meilin, 157, the New Telephoto graphic Lens, T. R. Dallmeyer, 161, on the Photographic Spectra of some of the Brightest Stars, J. Norman Lockyer, F. R. S., 261, Photographic Absorption of our Atmosphere, Prof. Schaeberle, 304, Eclipse Photography, M. *"To the solid ground  
Of Nature trusts the mind which builds for aye"*—WORDSWORTH

THURSDAY, NOVEMBER 3, 1892

### THE UNIVERSITY COMMISSION

THE University Commission is sitting frequently and has heard witnesses representing nearly every interest and every shade of opinion which have a right to be represented before it. We have no knowledge of the effect which the evidence laid before them has produced upon the minds of the Commissioners, but we are sure that it must largely depend on the view which they have adopted as to the nature of their duties. They may regard themselves as entrusted with the task of finding the terms on which a heterogeneous crowd of colleges and mechanics' institutes may be huddled together, called a university, and allowed to confer degrees on such conditions as the rivalries of competing institutions may permit when tempered by the moderating influence of Crown nominees, county councillors, representatives of the School Board and of the learned societies, and any other assessors whom fancy may suggest. Such a solution might no doubt secure peace in the sense that, wearied out by long debate and hopeless of a satisfactory solution, those who are most nearly interested in the question might at last be compelled to make the best of a bad job.

This, however, must be urged against it. That almost every teacher of eminence in London, together with a large number of those best qualified to represent the educational views of the provinces, have declared *a priori* that it would be unsatisfactory.

The other view which the Commissioners may take is that they are charged with the responsible task of defining the ideal system which would best provide for the supply of the higher education in London. That having defined this ideal they are then to proceed to show by what means the closest approximation to it which present circumstances will allow can be made, and so to fashion the constitution of the University as to ensure in the future a closer approximation still. That this is the wider and more statesmanlike view is beyond question, and we sincerely hope that the Commission will adopt it.

We may further hope that they will remember that although the new University should be able and willing to undertake all the multifarious duties which modern Universities have accepted as their own, the provision of the highest education and the doing all that in it lies for the advancement of learning must after all be the first and the highest duty of a University worthy of the name. As to the means which would best realize these ideals there cannot be a doubt. The present educational chaos must be reduced to order, the unwholesome rivalry between the London Colleges must be checked.

On this point Prof Rucker, in an address recently delivered at the Yorkshire College in Leeds, made some remarks which we cannot do better than quote in full —

"The great provincial colleges are grouping themselves into greater Universities. In the north Manchester, Liverpool, and Leeds have concluded a formal alliance. Negotiations are already in progress for the establishment of a similar confederation in Wales. The Midlands will no doubt follow suit. But if these afford, if in particular the north of England affords in the Victoria University, one of the happiest illustrations of the advantage of allowing free play to the tendencies which make for union no less than to those which encourage separation, we have, unfortunately, in London a striking instance of the harm which follows if the action of either the one or other is artificially restrained.

"The northern colleges were indeed happy in that the tendency to union was called into play while they were still in a sufficiently early and plastic stage of their history to yield easily to its influence. In London difficulties, which seemed far more serious half a century ago than they do to most of us now, have unfortunately retarded all centralizing action, till the sentiment and traditions which accumulate round institutions that have long moved independently, have enormously increased the inertia which tends to keep them in their separate paths.

"This is the more unfortunate, as if a new University of London is to be a really great teaching university, the relations between the London colleges must ultimately be closer than those which obtain between Manchester, Liverpool, and Leeds. The principle of recognizing as colleges of the University institutions for the teaching and management of which the University is not responsible, has worked and is working admirably in the north of England. It does not follow that it would succeed in London. There

is indeed a fundamental difference between the two cases. The colleges of the Victoria University are widely separated, and appeal to the strong local feeling of powerful and independent districts. A generous rivalry may therefore exist between them without ill result. Each should be left, as they have been left, to work out their own success with as little external interference as possible.

"It is sometimes argued that because the population of London largely exceeds that even of such districts as Lancashire or the West Riding, there ought to be room within it for the separate and independent institutions in which teaching of the highest type could be provided. This view ignores the importance of geographical separation, and unduly exalts that of the numerical magnitude of the population whose wants are to be met. If Manchester and Leeds were on opposite sides of the Irwell or the Aire, if they were connected by an elaborate system of over-ground and underground railways, then it would be more economical to concentrate, in one or the other, the higher teaching which must now perforce be given in both. The loss of time to the students in reaching the scene of their daily labours would be but imperceptibly increased, while the prestige of the colleges, great as it already is, their claims on the State, strong as they already are, would be enhanced in a proportion greater than that calculated by merely adding their separate reputations and resources. In a city of the size of London it is desirable to multiply institutions in which preparatory work of all sorts is undertaken, but I think it may be assumed as almost axiomatic that it is impossible, at present at all events, to create in one town more than one institution in which laboratories and lecture rooms and the other machinery of scientific instruction shall be provided on the large scale which the elaboration of the highest modern scientific teaching demands. In London, then, the teachers in almost all existing institutions feel the necessity for a combination of forces. They have expressed themselves as willing to be formed into battalions and regiments rather than to be left to carry on their work as isolated companies. I will not dwell on the fact that this desire could only be declared by men who were willing to risk their personal position for the public good, but I want you to observe how in this case also the work of decentralization, which began with the foundation of University College, London, has been followed and would have been far more effective had it been accompanied by a corresponding manifestation of centralizing force."

With these views we heartily agree.

If ever we are to have in London laboratories such as those which are to be found in Germany, it can only be if the higher teaching in each subject is concentrated in some one great central institution, and if rival colleges are allowed to combine their forces for the public good, instead of being compelled as at present to fritter them in suicidal competition.

Taking it for granted that all will admit that such an ideal would be the best if it could be realized, we believe that the possibility of its realization is chiefly doubted on two grounds, to neither of which any real importance is to be attached.

It has been supposed, in the first place, that those who advocate a policy of union among the London colleges think that this union must be carried out in all particulars immediately; and secondly that in order to secure this end it must be carried out by compulsion, even if the practical confiscation of the property of the existing colleges were necessary.

It need hardly be said that such a statement is a parody of the views of men who have had at least as much experience as their critics (of the tone of mind of the governing bodies of great educational institutions, and who therefore would be the first to anticipate the difficulties which such demands would inevitably cause).

No responsible body has, as far as we are aware, advocated more than the establishment of a University on a basis which would permit the union of the various colleges, in whose buildings the University teaching might at first be carried on, if the colleges were themselves willing that such a union should be effected. The advocates of union have all along been striving, not to attain an immediate and complete realization of their ideal University of London, but to prevent the Charter being drawn so as to make that realization impossible. It cannot be beyond the limits of human skill to frame a scheme which shall offer every inducement to the London colleges to effect an immediate fusion, and shall further provide that any approximation which may at first take place shall easily become closer in the future.

The Victoria University does not consist of competing colleges. A federal University of London would consist of colleges which from their mere local proximity would, whether they willed it or no, be necessarily antagonistic. Unless the Commissioners fairly grasp this fact and realize that they have it in their power to lay down the lines on which a great institution shall be founded in close connection with the State, which shall concentrate under one central directing power all the educational efforts which are at present partly wasted through want of joint action, they will have failed to make the most of a great opportunity, and will have frittered the forces which, if allowed free play, are competent to do for the higher education of London all that the best friends of London can desire.

#### THE STUDY OF ANIMAL LIFE

*The Study of Animal Life* By J. Arthur Thomson, M.A., F.R.S.E. "University Extension Manuals" (London: Murray, 1892)

THE chief aim of an "Extension Manual" as of "Extension lectures" is to stimulate interest and to spread information. In natural science, at any rate, it is impracticable through the medium of either Extension lectures or Extension manuals, to give that training which the student, be he specialist or generalist, can obtain only by practical work, aided by practical instruction. But there are a great number of people, some already busily engaged, others on the threshold of their life's work, who possess some interest in, and some information about, those matters, with the study of which scientific men are occupied. For them Extension lectures and manuals are a great boon, and to them Mr. Thomson's work on "The Study of Animal Life" may be cordially recommended. We trust it will stimulate them, as he would desire, to become themselves observers.

The work is divided into four parts, of which the first, entitled "The Everyday Life of Animals," deals with the wealth of life, the web of life, the struggle of life, the shifts for a living, the social life of animals, the domestic life of animals, and the industries of animals. The second part, on "The Powers of Life," contributed by Mr Norman Wyld, treats of vitality, the divided labours of the body, and instinct. The third part describes "The Forms of Animal Life" and includes chapters on the life-history of animals, and their past history as read in the geological record. The fourth and last part treats of "The Evolution of Animal Life" and, besides a discussion of the influence of habits and surroundings, and of heredity, gives a sketch of the evolution of evolution theories. Appendices on the relation of animal life to human life, and on some of the best books on animal life bring the work to a conclusion.

The general arrangement of the subject-matter is, as will be seen by the above summary, well and carefully thought out, and the facts given in elucidation of the varied tendencies of organic development are skilfully marshalled and are derived from the most trustworthy sources. The information given is therefore accurate and up to date. The only suggestion we have to offer in this connection is that a little more selective elimination might have been exercised. Some facts are given in so terse and condensed a form that no one but a zoologist could appreciate their value. If a considerable number of these had been struck out and the space thus gained had been utilized in expanding those that remained, the Extensionee would have been the gainer. "The Zoological Summary of the Animal Kingdom" (pp 210-272) might by some such process have been replaced by a sketch with more life and go in it. As it stands it will, by many readers, be gracefully skipped.

In such a work style is an important element. Here Mr Thomson is often exceedingly happy. He has imagination and a feeling for the poetic aspect of nature. But his imagination and poetry need at times just a little chastening. When he tells us that in birds "the breathing powers are perfected and economized by a *set of balloons around the lungs*," and that their brains "are not *wrinkled with thought* like that of mammals", when he speaks of the sponge as "*a Venice-like city of cells*", when he describes the ciliated cells of the windpipe as "*lashed cells*," or the embryonic membranes as "*birth-robes*," and when he says that in ponds subject to drought the organism often "*sweats off a protective sheath which is not a shroud*, and waits until the rain refreshes the pools", in these and sundry other cases of which these are samples, one may question whether the expressions which we have underlined are justified either by special elegance or by real helpfulness to a beginner. And this we say in no spirit of hypercriticism, but as desirous of aiding the author in what is by no means an easy task.

Somewhat deeper would be our criticism of sundry expressions which are of essentially human implication and which in our opinion should not lightly be applied to animal activities. Much is said of the "love" of animals for their mates when some such phrase as "sexual appetite" would be more appropriate. For example, concerning ants we read—"After this midsummer day's

delight of love death awaits many, and sometimes most." And in the analysis of the forms of struggle for existence, we have the "struggle between rivals in love." Again, of the cuckoo it is said that, "in spite of the poets, the note of this 'blessed bird' must be regarded as suggestive of sin"! And again, "It is not quite correct to say that the cuckoo-mother is immoral because she shirks the duties of maternity, it is rather that she puts her young out to nurse because she is immoral." It is true that Mr Thomson adds this footnote—"The student will notice that I have occasionally used words which are not strictly accurate. I may therefore say definitely that I do not believe that we are warranted in crediting animals with moral, æsthetic, or, indeed, any conceptions." We are glad to be thus assured. But why implant notions in the text which have to be eradicated in a footnote? Does not Mr Thomson know how easy it is to sow tares and how difficult to root them out?

Mr Norman Wyld's chapter on "Instinct" is short, but quite to the point. We hope that he may further observe and experiment in the field of comparative psychology, for he is fully alive to the peculiar difficulties of the subject, and there is a wide field before him in which the scientific workers are none too many. In criticizing Mr Lloyd Morgan's definition of instincts as "oft-recurring or essential to the continuance of the species," Mr Wyld says—"This is not quite satisfactory, for many actions that are instinctive are not oft-recurring, and many are not necessary to the preservation of the species." He does not show that there are any such actions which are neither the one nor the other. We have reason for supposing that he understood Mr Lloyd Morgan to say that instinctive actions were "oft-recurring *and* essential to the continuance of the species." But this he did not say.

In conclusion we may repeat that "The Study of Animal Life," though by no means faultless, may be recommended to Extension students and the general reader as, in the main, accurate, readable, and suggestive.

C. LL. M.

## VECTOR ALGEBRA

*Principles of the Algebra of Vectors*. By A. Macfarlane, M.A., D.Sc., LL.D., F.R.S. Edin., Professor of Physics in the University of Texas. Reprint from the Proceedings of the American Association for the Advancement of Science, Vol. XL, 1891, pp. 65-117 (Salem Press, Salem, Mass., 1891).

THIS is a very suggestive contribution to the foundations of the Algebra of Vectors as recently so strongly advocated in America by Prof Willard Gibbs, and in this country by Mr Oliver Heaviside.

The extensive use of quaternions among physicists has been prevented by the fact that the meaning of a product of vectors has been made to depend on the use of a vector as a quadrantal versor, and by the fact that this method leads to the square of a vector being negative. The advocates of the new algebra define a product of vectors independently and in such way that the square of a vector is positive. Rotations are expressed by means of dyadics, or ratios between vectors.

and the quaternion notion of a vector being also a quadrantal versor is not entertained at all

The author of this pamphlet devotes a portion of it to the consideration of quaternions, which he holds should form a distinct algebra by themselves, and he suggests a special notation for them. He restricts a quaternion proper to a *pure number* (a stretching factor) combined with a certain amount of turning. A vector, on the contrary, may be a quantity of any dimensions, possessing direction, with no suggestion of turning attached to it.

He clearly shows that the objectionable *minus* which occurs in scalar products in quaternions arises from the attempt to use the same symbol both for a quadrantal versor and for a vector, so that the laws established for dealing with one set of quantities may hold also for the other set, or for a combination of the two.

It may be worth while to notice that this minus sign of the quaternionists would disappear as an explicit symbol if they considered the second vector as being drawn from the end of the first, as AB, BC, and then took the angle ABC as being the angle between the vectors—that is to say, if, in a polygon of vectors, they were to define the angles between the successive vectors to be the *internal* angles of the polygon. Indeed, by many the internal angles of a polygon (or triangle) are considered as being *the* angles between the sides, though there is loss of real naturalness and of symmetry caused by so considering them. For instance, the connection between A, B, C and  $\alpha, \beta, \gamma$  in a spherical triangle would be greatly simplified if A, B, C were to denote the *external* angles. However, if we consider these internal angles to be the angles considered by the quaternionists, the reason for the square of a vector being negative appears at once, for if  $\alpha$  be the quantitative part (freed from the notion of direction) of a vector **A**, we have  $\mathbf{A} \mathbf{A} = \alpha^2 \cos 180^\circ$ , **A** and **A** being consecutive sides of the polygon which have straightened out till the internal angle between them is  $180^\circ$ .

It may therefore be contended that the quaternionists' *minus* is not quite irrational in vector algebra (though it cannot be said not to be inconvenient there), and that the advantage of being able to treat a vector as a quadrantal versor without having to establish a new set of formulæ far more than compensates for the loss of symmetry. On the other hand, the advocates of vector algebra without the *minus* would probably reply that they have to deal with vectors which are not in any sense the same as quadrantal or any other kind of versors, and that the imaginary completeness gained does not in any degree whatever compensate for the loss of naturalness and loss of symmetry involved in the *minus*.

The author differs from Prof Gibbs and Mr Heaviside in the mode in which he defines the product of two vectors, as he considers the *complete* product formed on the understanding that the multiplication shall obey the distributive law. He then finds that this complete product consists of a non-directed part, and of a directed or vector part, the former consisting of the product of the two quantities into the cosine of the angle between them, and the latter of the product of the two quantities into the sine of the same angle, having as axis the normal to

the plane containing the two vectors. The angle is the angle through which the first vector (occurring on the left-hand side of the product) would have to turn to make its direction coincide with that of the second.

Prof Gibbs and Mr Heaviside, on the contrary, define the scalar product and the vector product as if they were entirely distinct and independent quantities. Finally the same result is attained, but Prof Macfarlane's mode of introducing these partial products as arising naturally from applying the distributive law of multiplication would seem to have an advantage from the point of view of a student.

Prof Macfarlane dwells emphatically on the importance of considering *dimensions* of vectors, as well as their direction, and to emphasize this he separates his vector, not into *tensor* and *unit-vector*, but into *quantity* and *direction*. Thus in the equation  $\mathbf{X} = x\mathbf{i}$ ,  $x$  is the quantity, and  $\mathbf{i}$  denotes the axis. Hence the equation  $jk = i$  is not a violation of dimensions, but is merely a convention as to the interpretation of a composite direction, a convention, moreover, which could only be adopted in space of three dimensions, and is the statement that the plane in which  $j$  and  $k$  lie has its orientation sufficiently indicated by the normal direction  $i$ , with the further convention that the angle from  $j$  to  $k$  shall be considered positive.

The author's notation is novel, and forms a very important feature in his treatment of the subject. The scalar product of **AB**, which is  $ab \cos(\alpha\beta)$ , he calls  $\cos(\mathbf{AB})$  and the vector product he calls  $\sin \mathbf{AB}$ , its magnitude, irrespective of direction, being denoted by  $\sin \mathbf{AB}$ . Possibly an improvement in this latter would be to denote it by  $\sin \alpha\beta$ , and then the capital letter in the complete vector would become unnecessary.

The particular symbol used to denote a scalar or a vector product is a matter of secondary importance, but is a matter which must sooner or later be settled if vector-algebra is to come into general use. Lord Kelvin is of opinion that a function-symbol should be written with not less than three letters, and Prof. Macfarlane's notation obeys that law, and is moreover easy to work with, but is incomplete, being applicable to products of two vectors only. Mr Heaviside uses no prefix at all to a scalar product, but considers that **AB** means the scalar product. He uses the quaternionic expression  $\mathbf{V} \mathbf{AB}$  for the vector product. Prof. Gibbs uses no prefix for either, but denotes the scalar product by  $\mathbf{A} \cdot \mathbf{B}$ , and the vector product by  $\mathbf{A} \times \mathbf{B}$ . The three-lettered prefix seems the clearest in both cases to denote the special product intended, and the symbols  $\cos$  and  $\sin$  are more or less suggestive.

In forming a product of three vectors, Prof Macfarlane makes the convention that **ABC** shall mean  $(\mathbf{AB})\mathbf{C}$ , the combination commencing on the left. In his notation this product expands into

$$\begin{aligned} & (\cos \mathbf{AB} + \sin \mathbf{AB})\mathbf{C} \\ &= \cos(\cos \mathbf{AB} \cdot \mathbf{C} + \sin \mathbf{AB} \cdot \mathbf{C}) + \sin(\cos \mathbf{AB} \cdot \mathbf{C} + \sin \mathbf{AB} \cdot \mathbf{C}) \\ &= \cos(\sin \mathbf{AB} \cdot \mathbf{C}) + \sin(\cos \mathbf{AB} \cdot \mathbf{C}) + \sin(\sin \mathbf{AB} \cdot \mathbf{C}) \\ &= \text{vol } \mathbf{ABC} + \mathbf{C} \cdot \cos \mathbf{AB} + \sin(\sin \mathbf{AB} \cdot \mathbf{C}) \end{aligned}$$

which finally becomes

$$= \text{vol } \mathbf{ABC} + \mathbf{C} \cos \mathbf{AB} + \mathbf{B} \cos \mathbf{AC} - \mathbf{A} \cos \mathbf{BC};$$

where vol ( $\mathbf{ABC}$ ) denotes the volume of the parallelepiped of which  $\mathbf{ABC}$  are three adjacent edges. The only objection to this name lies in its suggesting that  $\mathbf{A}$ ,  $\mathbf{B}$ ,  $\mathbf{C}$  are linear vectors.

Here appears the defect in the author's *cos* and *sin* notation, in that it cannot be applied to the products of three vectors, or at least that the special reason for its use has disappeared, and the author does not suggest so applying it.

But there is a certain perspicuity attained by this very limitation of the *cos* and *sin* notation to the products of only two vectors, inasmuch as there can be no ambiguity in the meaning of an expression in which they occur, even if brackets are omitted or placed differently. Indeed, instead of *cos* ( $\mathbf{Sin\ AB\ C}$ ) the author writes *cos* ( $\mathbf{Sin\ AB\ C}$ ), which seems a curious use of the bracket. But *cos Sin\ AB\ C*, or preferably *cos\ C Sin\ AB*, is just as explicit, and even *cos Sin\ ABC*, though wrong to write as being puzzling, can only have the same meaning.

The author concludes with short sections on dyads and matrices, on scalar- and vector-differentiation, including scalar-differentiation of a quaternion. On the last page are a series of propositions relating to the addition of scalar and vector quantities situate at, or passing through, specified points.

The pamphlet is confined solely to statements of principles and the section devoted to dyads and matrices is very condensed, so that it is not in any sense a text-book for students. It is rather a synopsis of the subject, with the introduction of a special notation which the author has found useful. A text-book of vector algebra, with examples showing its application to problems in geometry, mechanics, and general physics, and contrasting the method with the Cartesian method of treating the same problems, is much needed, as many physicists are becoming interested in the new algebra, owing in great measure to Mr O Heaviside's able exposition of its principles and applications in the *Electrician* and elsewhere.

### THE LAKE OF GENEVA

*Le Léman Monographie Limnologique* F A Forel  
Tome Premier. (Lausanne F Rouge, 1892.)

PROF FOREL has been for some years occupied in studying the Lake of Geneva, and has now published the first instalment of the fruits of his labours. The work, when finished, is intended to be a complete monograph of the history of a single lake, and will be a most important contribution to an interesting branch of physical geography. In the present volume the geography, the hydrography, the geology, the climatology, and the hydrology of Lake Léman are discussed, after some introductory matter relating to the instruments employed in sounding with other preliminaries. But, though only a single volume, the work embraces so many questions that we must, for want of space, confine our notice mainly to one, which, of late years, has attracted the most attention, at any rate in this country, viz. What has been the origin of the lake basin? Was it formed by the old Rhone glacier or in some other way? The especial value of Prof Forel's memoir is the number of new facts which it brings to bear on the problem thus propounded.

NO. 1201, VOL. 47]

The Lake of Geneva, however it may have been caused, is more modern than the middle of the Miocene period. "Le lac n'existait pas encore, la vallée du Léman n'était pas même indiquée quand la mer helvétique déposait les mollasses d'Epalinges et du Mont." Its slopes, and almost certainly its bed, are covered with glacial deposits, of later date than the formation of its basin. Terraces around its shore indicate that its waters once reached a higher level, the greatest elevation which can be identified with certainty, being about 30m above the present surface. The next pause was at 10m, after that the lake sank (the fall always being rapid) to its present level. Traces of still higher terraces are to be found on the north shore, but as these neither can be identified on the opposite side, nor correspond with any natural barrier in the course of the Rhone below the lake Prof Forel doubts whether they indicate old levels of its waters.

Lake Léman consists of two basins. The first and larger extends from the embouchure of the Rhone to the narrow of Promenthoux. At the east end the slope of the cone of alluvium deposited by the Rhone in no part exceeds 25°. First comes a zone of very shallow water off the actual shore line, to this succeeds a more rapid slope, which gradually eases off as it descends. The current of the Rhone has made and maintains a well-marked channel in this mass of detritus, and the contour lines are affected down to 250m. At the embouchure of the Dranse, on the south shore, another alluvial cone has been deposited. This, however, is rather steeper, but it is much smaller, and does not perceptibly affect the course of the subaqueous contour lines below about 200m. On the north side of the basin the slope varies. Under the walls of Chillon the descent is rapid, amounting to 137 in 100, it is nearly the same near St Gingolph on the opposite shore, doubtless indicating submerged crags, but it is generally more moderate. West of Vevay it is about one in four, whence it changes gradually to one in ten opposite to Ouchy.

West of this port the descent is still more gentle, and so it continues round the western end of the basin, the lip of the latter being 75m below the surface. The contours of the south side correspond generally with those of the north, and the form of the basin is evidently related to the geology of the district, being narrower and steeper among the harder rocks at the eastern end. The deepest part is a large rudely triangular area, the apex pointing towards the west, and the base lying roughly north and south, extending from almost opposite to the embouchure of the Dranse to near Lutry. All this area is an almost level plain, for it is wholly below the 300m. contour line, but the greatest depth obtained was only 309.7m.

The Petit Lac may be described as a comparatively narrow and shallow trough, rising very slowly from a depth of about 70 to 50 metres, and then gradually mounting to the embouchure of the Rhone, its bed being slightly interrupted by five small shallow basins, which roughly speaking, have a linear arrangement, but their floors only sink four or six yards at most below the general level.

The lake to some extent is still held up by the huge mass of gravel brought down by the Arve, through which the two rivers have now cut their channels on either side of the plateau of La Bâtie below Geneva. But it is

in the main a true rock basin, though its bed no doubt is concealed beneath glacial deposits and the finer mud brought down by rivers. This alluvium has been studied by Prof. Forel, but into the matter we are unable to enter.

Both the origin of lake basins in general and of that of Léman in particular are carefully discussed by Prof. Forel. He examines, only to reject as attended by insuperable difficulties, the hypothesis that it was excavated by the old glacier of the Rhone. He shows that the subaqueous portion corresponds in its general features with a river valley, and is only a prolongation of that of the Rhone. This valley was first defined at a very early period in the uprising of the Alps, its excavation progressed with their growth, it was practically completed at a time when they were higher, perhaps by some 1000 m., than at present. Then the lake was formed by a general subsidence of the mountain region, the lowland remaining comparatively unaffected. The movements of the parts depressed may have been to some extent differential, but this, in Prof. Forel's opinion, is not a necessary assumption. To us, however, it appears that it would be very difficult to explain the rock barrier at St. Maurice between the upper and lower plains without some amount of differential movement. Prof. Forel's view, of course, is not novel, for it has been long maintained in England as a general explanation of the greater Alpine lakes by a few geologists, who never bowed the knee to the glacial Baal. With their writings, however, Prof. Forel does not appear to be acquainted, though they appeared in publications generally accessible.

The remainder of the present volume is occupied by a discussion of the temperature, rainfall, and general hydrology of the Lake Léman region. It is full of interesting facts and discussions, which we would gladly notice did space permit. The book is well printed, and contains many illustrations, together with a large map of the lake on which the subaqueous contours are depicted. If the book were less diffuse its scientific value would have been greater, but Prof. Forel pleads in excuse that he aimed at writing a volume which would be also acceptable to the general public, or in other words, would combine meat for men with milk for babes. As a comprehensive history of a lake is a great desideratum, it would be ungracious to find fault with Prof. Forel's very natural desire to secure a large number of readers and of purchasers.

T. G. BONNEY

#### OUR BOOK SHELF

*Horn Measurements and Weights of the Great Game of the World, being a Record for the use of Sportsmen and Naturalists.* By Rowland Ward, F.Z.S. (London: Published by the Author, 1892.)

IN these days, when every one is striving to "beat the record," it is only right that sportsmen should have clearly put before them the results already arrived at as regards the size of the trophies and the weight of game animals already obtained by their brother Nimrods. No one is in so good a position to do this as Mr. Rowland Ward, to whose well-known "jungle" in Piccadilly all the leading shooters of the present day send their "heads" to be mounted and their "skins" to be stuffed. It is, however, much to be regretted that Mr. Ward did not take into his councils some brother "F.Z.S." more

versed in scientific knowledge than himself when he prepared this volume, or at any rate did not have the proof sheets revised by some zoologist with a good knowledge of the Mammalia. The consequence of this want of foresight is that the nomenclature and localities upon which the importance of the records entirely depends are in a very confused state, and in many cases quite erroneous.

Take the Deer (Cervidae), for instance. Of this family a very correct and accessible list, drawn up by the late Sir Victor Brooke, has been published in the "Proceedings" of the Zoological Society for 1878, which Mr. Ward would have done well to follow. But we find under the Sambur (*Cervus aristotelis*) a head from "Java," where this species certainly does not occur, recorded in the list. Next to this (p. 10) comes the "Central and South Indian Sambur, *Rusa hippelaphus*" (whatever this may be), but three out of the four specimens assigned to it are from Nepal! On the other hand, several heads from Java are attributed (p. 22) to *Cervus rusa*, which is merely a synonym of *Cervus hippelaphus*.

The heads of the large Deer of the Caucasus obtained by Mr. St. George Littledale are assigned (p. 28) to the Red Deer (*Cervus elaphus*). But we have good reason to know that they really belong to the Persian Deer (*C. maral*), quite a different species.

Looking over the list of Antelopes, we find similar errors prevalent, though perhaps not quite to so great an extent. The specimens of the Chiru (*Pantholops hodgsoni*) are assigned to "India," whereas this Antelope is only met with in the snow-fields of Ladakh and Tibet. Nor can the "Takin" (*Budorcas taxicolor*) be properly stated to be from "India." It occurs only in the Mishmi Hills on the frontiers of Assam.

These and many like mistakes are the more serious as Mr. Ward's volume is well got up, nicely illustrated, and likely to be frequently used by the sporting naturalist. But the statements contained in it cannot be relied upon for scientific accuracy.

*Der Peloponnes Versuch einer Landeskunde auf geologischer Grundlage.* Von Dr. Alfred Philippson. (Berlin: R. Friedländer and Son, 1891-1892.)

GREECE has hitherto been interesting mainly to scholars, archaeologists, and lovers of art, and no doubt it is from their various points of view that the country will always be most eagerly studied. The subject, however, has also elements of attraction for students of natural science, and it is to these elements, so far as the Peloponnese is concerned, that Dr. Philippson has sought to do justice in the present work. His results have been obtained by direct personal observation, and are set forth with admirable clearness. The book is divided into two parts, the first of which is called "special," the second "general." In the "special" part the author deals with particular regions of the Peloponnese, in the "general" part he presents an account of the peninsula as a whole. Dr. Philippson is a careful and accomplished geologist, and has been remarkably successful not only in throwing fresh light on the geological phenomena of the country, but in showing their relation to the various orders of facts which come more especially within the province of the geographer. He has also excellent chapters on the forms and phenomena of the surface, on climate, on vegetation, on the animal world, and on the population. In dealing with the last of these subjects he has much that is valuable to say about productive industry, means of communication, density of population, and towns, villages, and other settlements. The interest of the work is greatly increased by maps and profile sketches.

*Traité Encyclopédique de Photographie.* By Charles Fabre. (Paris: Gautier-Villars and Sons, 1892.)

IN a previous number of NATURE (vol. xlv. p. 464) we noticed the first part of the supplement which M. Fabre

proposes to bring out triennially. The present two volumes form a continuation, and extend as far as § 5 of the second chapter in the second book. The author proceeds on the same lines as formerly, and places before the reader in a concise way all the new methods of development, measuring lenses, apparatus, &c., from the particulars of constitution which characterize developers down to the latest form of kodak or the camera. Not only is each subject treated with the greatest care, but illustrations are numerous distributed. That which will add great value to the work as a whole is the insertion of references, for what, after all, is more annoying than having to wade through a great quantity of literature when the presence of one or two words would have eliminated all trouble? W

*The Reliquary Quarterly Archaeological Journal and Review* Vol VI (New Series) (London: Bemrose and Sons, 1892)

THIS volume consists of the four numbers of *The Reliquary* which have appeared during the present year. The contents include many things which do not quite come within the scope of *NATURE*, but it is satisfactory to be able to note that the writers, speaking generally, have done their work in a thoroughly scientific spirit. Mr J. Lewis André contributes an interesting and well-illustrated paper on leather in the useful and ornamental arts, and a clear account is given by the editor of a part of an early dial, bearing runes, which he was lucky enough to find some months ago in the churchyard of Skelton, Cleveland. An illustration gives a good impression of the general character of the stone, the runes on which, according to Canon Browne, are "Danish." Among the other papers are two articles, by Mr D. A. Walter, on ancient woodwork, and a discussion, by the Rev A. Donovan, of some of the problems connected with the career of Columbus.

#### LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of rejected manuscripts intended for this or any other part of *NATURE*. No notice is taken of anonymous communications.]

##### Nova Aurigæ

ON October 5 the Nova Aurigæ was again observed under favourable circumstances, and the observation as to precautions in focussing necessary on account of chromatic aberration of the refractor was amply verified [*NATURE*, September 22, p. 489, in which note two corrections should be made: eighth line, for "varying" read "ranging," and fourteenth line, for "(P F)" read "(? G)"]. The line near C was distinctly seen at times, but the blue and violet lines observed on September 14 were not seen; the three green lines were very distinct.

On October 14 the red line was much fainter, but there was an obvious bright line in the yellow, which may be the line which Dr. Copeland estimated as 5801 on August 28 [*NATURE*, September 15], or may be that which has been measured several times at the Lick Observatory (*Astrophysics*, October, p. 717), and appears to have a wave length of about 575. It had escaped my notice before, but I was induced to look most carefully in the yellow by considerations arising out of an attempt to reconcile Mr. Barnard's observations of apparent nebulosity-surrounding the Nova, as seen in the 36 inch refractor at Mount Hamilton, with my own observations of September 14. Mr. Barnard's "stellar nucleus" was the difficulty. There appears to be no doubt that the Nova is emitting a spectrum similar to that of a planetary nebula, but it seems to me necessary to have further spectroscopic evidence before it is established that nebulous extension can be seen, if it is to be seen with a simple eyepiece, it must be looked for in a reflecting telescope, as the following considerations will show.

Prof. Keeler's study of the chromatic correction of the Lick

Refractor shows ("Pub. Ast. Soc. Pacific," Vol. II, p. 164) that the circle of aberration of F light on the focal plane for the D line has a diameter which is in terms of the focal length 0.000349. We may take this diameter as very nearly that of the circle of aberration of D light on the focal plane for the F line. Thus if a star emits only D and F light, and the F light is focussed, then the D light will fill a circle nearly 7" in diameter, and the star will look like a planetary nebula with a stellar nucleus. If the star emits light of wave lengths 500 and 575, then interpolation based on Keeler's measurements shows that round a stellar nucleus in the focus for wave length 500 there must be a circle of aberration of nearly 4" diameter.

Mr. Campbell found lines of wave lengths 500 and 575 in the spectrum of Nova Aurigæ with respective intensities 10 and 1. Mr. Barnard describes the appearance of nebulosity as "pretty bright and dense," and as measuring 3" diameter. My own inability to see either the circle of aberration for the yellow line when the green was focussed, or the alleged nebulosity, may be explained in several ways (e.g. smaller aperture of object glass, climatic conditions, &c.). The spectroscope could probably decide the question at Mount Hamilton by showing whether the minimum length of any of the lines is that corresponding with 3" diameter on the slit. I have not been able to do more than observe that the yellow line is not visible when the 500 line is focussed on the slit of a spectroscope having an effective dispersion of two 60° prisms. H. F. NEWALL

Observatory, Cambridge, October 24

#### Formation of Lunar Volcanoes

WHILE we have, on the lunar surface, a series of markings so evidently volcanic that no one thinks of applying any other term to them, we have on the other hand no explanation of their mode of formation which will stand examination. The explanation given by Messrs. Nasmyth and Carpenter in their splendid work on the moon, founded upon explosive expulsion of lava, fails to satisfy the mind when applied to wide craters with a low wall such as Shickard or Grimaldi, of which there are so many on the moon, and which look more like some disturbance in a semi-liquid surface than an accumulation of volcanic debris.

The umbrella-like eruption figured in Messrs. Nasmyth and Carpenter's book does not represent any phenomenon within our experience, as the erupted material (unless light enough to be driven by wind) invariably falls back into the neighbourhood of

the vent, and we could not conceive of its being shot neatly out twenty-five miles on every side to form the familiar ring.

An explanation of the mode of formation founded upon lunar tidal motion occurred to me about seventeen years ago, from observations on a cooling slag, but until the recent publication of Mr. Darwin's work on the history of the tides I was doubtful if that force were sufficient to account for observed results.

I had noticed that the rise and fall of a fused slag through holes in its solidifying crust, formed craters exactly like those in the moon, and I enclose a photograph of a piece of that slag in which is reproduced all the salient features of the lunar surface.

The mode of formation was as follows:—

The fused liquid (which was potash "black ash" containing a mixture of substances of very varied melting point) was still giving off some gas, which escaped as at *a* in Fig. 1, building up

a miniature crater as at *b*, *c*, *d*. But the crater vent becoming intermittently choked, the accumulation of gas beneath the crust caused the liquid "lava" to rise through any neighbouring holes as at *e*, *f*, giving rise to a ring crater. The pressure of the accumulated gas now drove out the obstruction in *a*, when the liquid lava receded in *e* as at *g*. This intermittent action went on till the crater *a* was built up—entirely by "rise and fall" (as of a tide), no gas escaping at this hole.

In the case of the moon the rise and fall would be caused by the tidal motion of the still liquid interior. The solid crust would resist the periodic rise of the liquid interior, and the liquid would well through the crust and recede again as the wave passed.

When the crust was thin, and the lava very liquid, the large ring structures would be formed, as the lava would flow far, but

FIG. 2.

as the crust got thicker and the lava more viscid, the more striking craters like Copernicus would be built up. When the vent was very small, or the lava very viscid, the exuded lava would build up mountain ranges, or peaks like Pico, as it could not flow far, and would be cooled too much to allow of its flowing back with the ebb tide.

The existence of the cause proposed by Messrs Nasmyth and Carpenter, viz., expansion on solidification, is very doubtful. The proof they adduced was that a piece of solid slag would float on liquid slag. But when slag solidifies it becomes filled with small cracks, which doubtless contain air, and so aid in the flotation. When I was working at this subject I had some slag poured into an iron mould kept cool by immersion in water. When the slag had cooled a distinct depression was seen on the upper free surface, showing that the slag had contracted during solidification. No doubt its contraction or expansion will depend upon its composition, and we do not know the composition of the moon's surface, but we need not depend upon a doubtful property for an explanation when a set of conditions have existed which must have yielded an ample force for the production of the observed results.

In the photograph marked Fig. 2, at *a* can be seen a crater

with a raised floor and a central cone, at *b* a crater filled to the lip like "Wargentia," while on the plain near *b*, and round the open crater *c*, will be seen numerous minute craters, as on the moon's surface in the neighbourhood of "Aristotle" or "Copernicus," while in other photographs are seen walled plains like the "Mare Crisium," so that all the important features of lunar topography are reproduced in this slag, and there are many minor points of agreement which cannot be gone into in the limits of a letter.

Although I have always considered the tides the cause of the wonderful lunar configuration, I was not satisfied that that cause alone was of sufficient magnitude, till the work of Mr Darwin placed the matter in such a clear light that I now venture to submit the idea to your readers as a feasible explanation of the familiar lunar features  
J B HANNAV.

#### On the Need of a New Geometrical Term—"Conjugate Angles"

IN geometrical discussions, such as arise out of a great variety of physical problems, it is frequently necessary to refer to an acute or obtuse angle *A* as being equal to another acute or obtuse angle *B*, because contained by two straight lines which are respectively perpendicular to those containing the angle *B*. Such a statement of the reason of the equality is, however, cumbersome. Sometimes, indeed, such angles when acute might be described as equal because they are the complements of equal (because vertically opposite) angles, but it will often happen that the figure does not show the vertically opposite angles that would be referred to.

I should be glad to know whether there is any term expressing the relation in question in use among either English or foreign writers, and, in default of such, would suggest that such angles be called *conjugate*, or if greater precision is required, *rectangularly conjugate*, the general term *conjugate* to be used when we wish to refer to an angle *A* as equal to an angle *B* because contained by sides whose directions are the directions of the sides of *B*, after each has experienced an equal and similar rotation in the plane of the diagram, whether the rotation is through a right angle or not.

The shorter inclusive term *conjugate* could always be used for the less general but longer term *rectangularly conjugate*, when brevity was aimed at.

#### Printing Mathematics

THE main features of mathematical work that give trouble in printing are three—the expressing of (1) fractions, (2) powers, (3) roots.

(1) To simplify the expression of fractions we have the solidus suggested by Sir G Stokes. But the solidus has been hitherto much less used than it might be, on account of the uncertainty as to how far its influence reaches in any expression more complicated than the simplest fractions. This uncertainty can easily be removed, and the usefulness of the solidus greatly extended by defining more definitely its exact meaning. This is done in the simple conventions proposed below.

(2) To express the process of involution, the sign  $\wedge$ , suggested by Mr C T Mitchell in the *Electrician*, is more concise and clearer than that mentioned by Prof S P Thompson in *NATURE*. And Mr Mitchell's sign, if defined by conventions similar to those applied below to the solidus, is capable of a like extensive application.

(3) To express roots we have the sign  $\sqrt{\phantom{x}}$ . But, when accompanied by a horizontal line above to show the extent of its influence, this sign also requires special spacing. But it can be brought into line with the rest by the use of the same conventions.

Taking then for

- |                         |    |   |                      |
|-------------------------|----|---|----------------------|
| a. the sign of division | .. | . | $\div$               |
| b. " " involution       | .. | . | $\wedge$             |
| c. " " evolution        | .. | . | $\sqrt{\phantom{x}}$ |

we may use each of these signs in either of two ways:—

I. Simply as a sign of operation, in which case it can influence only the quantities immediately adjacent to it.

II In a double capacity—

(1) As a sign of operation,

(2) As one end of a bracket, of which the other end is | this bracketing influence may be directed either forwards or backwards, or both ways at once

### Examples

#### A. Division

$$\begin{aligned} a + \frac{b}{c} + d &= | a + b/c + d |, \\ a + \frac{b}{c+d} &= a + b/c + d |, \\ \frac{a+b}{c+d} &= | a + b/c + d |, \\ a \frac{b}{c} d &= ab/cd, \quad a \frac{b}{cd} = ab/cd |, \\ \frac{a}{b+c} (d+e) &= a/(b+c)(d+e), \\ (b+c) \frac{a}{d+e} &= a/(b+c)(d+e) |, \\ \sin \frac{\theta}{n} &= \sin \theta/n, \quad \frac{\sin \theta}{n} = | \sin \theta/n | \end{aligned}$$

Continued fractions also can readily be brought into one line by this notation—

$$\frac{a}{b+d+\frac{c}{e}} = | a/b + c/(d+e) + f/g |,$$

#### B. Involution

$$\begin{aligned} a^b &= a \setminus b, \quad a^{-b} = a \setminus -b, \\ (a+b)^c + d &= | a + b \setminus c + d |, \\ a + b^{-1} d &= a + b \setminus c + d |, \\ (a+b)^{c+d} &= | a + b \setminus c + d |, \\ (a+b)^{c+d} &= | a + b \setminus c + d/e + f | \end{aligned}$$

$a \setminus b/c$  and  $a/b \setminus c$  are ambiguous, but  $| a \setminus b/c = \frac{a^b}{c}$ , because  $|$  being unnecessary for  $\setminus$  in this case, can apply only to  $\frac{(a+b)^c}{d}$  is  $| a + b \setminus c/d$ , two vertical lines being required.

Similarly  $| a/b \setminus c = \left( \frac{a}{b} \right)^c$ ,  $a/b \setminus c = \frac{a}{b^c}$ ,  $a \setminus b/c = \frac{a^b}{c}$ .

$$a \setminus b \setminus c \setminus d = a^{b^c d}.$$

#### γ Evolution—

$$\begin{aligned} \sqrt[n]{a+b+c} &= | n \sqrt{a+b+c} |, \\ \sqrt[n]{a+b} \sqrt{c+d} &= | a + b \sqrt{c+d} |, \\ \sqrt[n]{a+b} \sqrt{c+d} &= | a + b \sqrt{c+d} |, \\ a + b \sqrt{c+d} &= a + b \sqrt{c+d} |, \\ a + \sqrt{b} c + d &= a + | b \sqrt{c+d} | \end{aligned}$$

In some cases lines of differing thickness might be advisable, for instance—

$$\frac{b^b}{(c+d)^a} = | b \setminus 1/2 | / c | d + e \setminus 3 |$$

There are many other ways in which this notation might be used; but the above will suffice to illustrate the advantages of it. And these advantages are substantial. It enables the work to be printed in the same space as ordinary letterpress, and thus avoids the special spacing, from which nine tenths of the troubles in mathematical printing arise. It requires no new types, except, perhaps,  $\setminus$ , and each of the signs used is suggestive of the original mode of writing for which it is a substitute. It can be used without confusion in conjunction with all ordinary brackets. How far this notation would suit very complicated expressions, is a point that would have to be determined by experience; but for printing mathematics of ordinary complexity it would be useful in economizing space and diminishing the risk of printers' errors without any sacrifice of clearness.

Cambridge, October 27.

W. CARRIE.

### "Sunshine"

IN acknowledging the courteous criticism and the kind remarks which "C. V. B." has been pleased to make about my little book, may I be permitted to comment on one or two points, which I think he has imperfectly understood from the text. We all know that when "C. V. B." undertakes to review a book, he does his work in a thorough and searching manner, and from his critique it is evident that "Sunshine" has been well read. Notwithstanding this, in one or two of the instances selected for criticism the meaning, at once simple and obvious to a little child, who neither knows nor suspects any other, seems to have missed him, presumably because he knows all the bearings of the subject. Thus it is sometimes a disadvantage to be learned. Of this I propose presently to give an instance in the order which it occurs.

After poking fun at me, because, the "Sunshine" course being ended, Tommy meets King Sol face to face and "has it out with him," my critic proceeds to discuss the limits within which the imagination may be appealed to as a factor in scientific education, and while I agree with him in the main, I am tempted in passing to remind him of what Tyndall terms "the scientific use of the imagination," to which the clearness and (to me) the charm of his own lectures is largely due. Be that as it may, in one of "Nature's Story Books" I feel fully justified in employing, *within the limits of scientific accuracy*, any or all of the powers of the mind, which shall help children and others to *realise* the relation they bear to their surroundings, assured that in a course based upon some hundreds of experiments synthetically worked out and deductions made—a course whose main object is to lead children to go direct to Nature, *via* experiment, for their knowledge, there is little danger that the imagination be cultivated at the expense of the reasoning faculties. The experience of the writer is that the children attending the lectures became extremely critical—a state of mind which, although of inestimable value in acquiring knowledge, is not one of the happiest in other respects. Therefore it was thought desirable to provide them with some necessary ballast, and this is my defence of the hypnotic visit to the moon, and the other two chapters to which the critic alludes.

Natural science apart, it seems to me that the tendency of the school teaching of to-day is calculated rather to make children hard and matter of fact. For this reason I have endeavoured in these Sunshine Stories to interest children in the poetry of their common lives, myself playing somewhat the role of an optical instrument, presenting images sometimes real, sometimes virtual of those physical beauties which touch them at every point. The fact that "C. V. B." recognizes in "Sunshine" the *realism* which the "picturesque language" was intended to convey, disposes of the case of my Cape Town reviewer, who mildly insinuates that I have been guilty of some *fraud* upon little children in calling "Sunshine" a story-book. Therefore I am the more glad that "C. V. B." agrees with me that the mathematical side of these questions should not be obtruded. There are so many excellent text-books which supply that information for older pupils. I need not say that I shall be most happy to add the exception in the case of the rainbow. I thank him also for pointing out a passage in the notes where an additional clause is necessary, owing to the transposition of a paragraph. But I take exception to the statement about the top, for it is evident that the experiment is not made under the same conditions as that which "C. V. B." has in mind, because my boys get green and he gets (he says) white, or nearly white. The home experiment reads "I am giving each of you squares of coloured paper to take home, then you may have the papers to put on your tops—e.g., cover half blue and half yellow, spin the top and you will see green." A note on page 341 refers to the kind of paper. Now it seems to me from the expression "painted disc," which "C. V. B." has made use of, that possibly he may have had Clerk Maxwell's top in mind when he wrote.

When I say to a boy, "Here are two squares of paper, one blue and one yellow; when you've done so and so, you can have the paper to keep—cover your top, half yellow, half blue, &c.," the lad understands me, and when I am not there he takes out his halfpenny whip-top, tears a piece of the blue paper, and rendering it slightly adhesive hammers it down on the top with his right fist, he tears a similar piece and treats it in the same way, and so on until he has covered half. Then he takes the yellow paper and covers the other half with irregular patches of yellow. He spins the top and sees green.

How different is this from Clerk Maxwell's top. Clerk Maxwell selected for his top the purest of paper and pigments. He endeavoured to match the spectral colours (considerably diluted). He selected a scarlet red with a tinge of orange like *orange-red vermilion*, lying in the spectrum one-third the way towards D, between the lines C and D. His green was one fourth the distance from E, between E and F, and resembled emerald green. He also selected a blue violet midway between F and G, which was imitated by that purest of colours—ultramarine. Now let us try the given experiment under the favourable conditions guaranteed by Maxwell's discs, viz., the purest of colours painted on Whatman's paper. Taking up a disc of ultramarine and another of pale (not orange) chrome yellow, and concealing half of one disc behind the other, on rotating the compound disc so that the eye shall receive simultaneously blue and yellow light, the result is not white or even practically white, but a *grey, tinged with yellow*. By a careful adjustment, hiding more of the yellow and exposing more of the blue (thereby altering the proportions of the text), it is possible to get rid of this yellowness and to obtain an absolutely neutral grey which it might be possible to persuade some grown up people represented white, but which on analysis yields  $71\frac{1}{2}$  per cent black to  $28\frac{1}{2}$  per cent white. This may be proved by revolving a disc of black and white sectors in the above proportions, the results in each case being identical. But even this result, unsatisfactory as it is, does not apply to the passage quoted in the text, in which no special conditions are observed. I maintain what is easily proved by experiment in less time than it takes to write it, that when ordinary colours, *e.g.*, gamboge and Prussian blue, are used, the residual light is green.<sup>1</sup>

I fear that already this letter is too long, and since I do not wish to monopolize the space kindly placed at the disposal of your correspondents, I must defer the consideration of the annotations on soap films. The other points are dealt with in the preface.

AMY JOHNSON

52 Lower Sloane Street, S W, October 12

I do not think that the observations on my review of "Sunshine" require more than a very short answer.

I considered that the authoress had not by any means cleared the confusion which usually exists as to the meaning of the expression "mixing of colours." It is applied both to the case where two or more colours are seen superposed, *e.g.* by spinning coloured paper where the resultant tint is due to the sum of the separate colours in the constituents, and to the case of mixed pigments where the resultant tint is that which is common to the constituents. Now as the common "paint box" rule says that blue and yellow make green, that is that blue and yellow pigments mixed produce a green pigment, it seems to me very misleading to say "Cover half (of your top) blue and half yellow and you will see green." Of course it may happen that the slight departure from white which will be observed may be in a greenish direction, but it may also be inclined towards pink, or, for anything I know, towards any other colour. The one thing it will not do, however, is to make a green such as is obtained by mixing the pigments, and such as I fancy from the context any one would expect. C V B

### The Photography of an Image by Reflection

THE great utility of spark photography for obtaining time records of quickly-moving objects must be apparent to all who know the experiments of Mr C Bell, Prof Boys, and Lord Rayleigh. By means of spark photography the shadow of any object such as a jet of water, a flying bullet, or a broken soap film can be produced with perfect definition. The shadow of the moving object illuminated by an electric spark is thrown on to a sensitive plate in a dark room, and the plate is developed in the usual manner. The process of spark shadow photography will be found, I believe, of great service in physiological research. With a view to try this I attached a long sensitive plate to the traversing carriage of a chronograph; the moving carriage closed and opened the primary circuit of an induction coil at pre-

arranged equal intervals of time. In front of the moving plate a frog's heart was placed in a slit on a screen, at each break a shadow of the heart was thrown on to the plate by means of the induced spark. By this means thirty positions of the heart were registered, the pictures were all sharp and clear. I have also used the same method for photographing the movements of insects.

Since these experiments which I showed during the University Extension Meeting in Oxford this year, I have made several attempts to get spark photographs of the front view of objects (not their shadows). In my first experiments the objects were illuminated by an electric spark, the image being received on a plate in an ordinary camera. I found that so much useful light was shut off by the lenses that only a dim picture could be produced. A quartz lens was next tried and the results were rather better. I then determined to use no lens, but in its place a silvered mirror. A concave reflector made by silvering a concave lens of about 10 c.m. diameter was so placed that it reflected the image of a white paper star 7 c.m. diameter, revolving about 60 times in a second, on to an ordinary photographic plate, the total length traversed by the light being 80 c.m. The star was illuminated with a spark exactly similar to that used in the previous experiment, on development a good picture of the star came out. The reflector was neither well made nor well silvered. The idea was suggested by observing some spark photographs I obtained of waves on the surface of mercury reflecting light. When a steady light is used a photograph of any object is readily obtained by reflection from a suitable mirror. Probably a steel surface would be best. The mirror and plate were placed in a long box provided with a hole at one end through which the light reflected from the object passed. A few experiments made on living objects to test the time of exposure in Reflection Photography showed that in order to avoid over-exposure, a very rapid shutter must be used.

FREDERICK J SMITH

Trinity College, Oxford, October 25

### Induction and Deduction

As your correspondent invites discussion on this subject I hope you will allow me to repeat in a new form the views I expressed upon it in your columns some months ago. I quite agree with Mr Russel in maintaining that "true induction is utterly unable to yield us any conclusion that is more than probable and approximate," understanding by induction inference from one or more special cases to a more general rule. But on the other hand it appears to me that Miss Jones's criticism is quite destructive of Mr Russel's interpretation of geometrical reasoning. The point which both have missed I believe to be this, that a proposition stated in given words, such as the enunciation of Euclid's *pons asinorum* does not always and to every one convey the same information, and if it is meant in one sense its degree of reliability, and the method by which it must be proved, will be quite different from what they would be if it were meant in another. There are at least three different kinds of interpretation which may thus be put upon the proposition. It may mean (1) the triangle used to illustrate this proposition has equal sides, therefore it has equal angles, or (2) I have conceived a triangle which has equal sides, therefore I have conceived one which has equal angles, or (3) the connotation ascribed by the adjective "isosceles" implies the connotation "having equal sides."

It is not necessary for me here to dwell upon the distinction between the first two interpretations, but the difference between either of them and the third is that this latter gives us no information about any real thing or concept, but only about what is implied by using certain terms. And this latter kind of information clearly does not require to be based upon any real knowledge of things, but may be based solely on definitions of words. Arguments with propositions interpreted only in this sense are what I call symbolic arguments; and symbolic conclusions therefore give no real information unless they can be interpreted by the aid of real assertions, such as "I can conceive," or "There actually exist, things possessing the connotations ascribed to these terms by their definitions."

If this distinction has not before been recognised, it is because in most logical discussions we can in this way give a real meaning to our arguments. In elementary geometry, for example, we can—with more or less effort—conceive things, or even actually draw them, which answer to our definitions with sufficient accuracy. And, indeed, the reason why "Euclid"

<sup>1</sup> The purport of the experiment will be best understood if I state that it follows a series of chapters on colour, viz. the rainbow, the spectrum, its decomposition by refraction and by reflection, while the last chapter discusses and explains, with experiments, the question of spectral lights versus pigments. The common surface papers, which the children are daily in the habit of using, are then analysed by the prism, and found to be anything but monochromatic.

and "Newton" are generally considered to yield a more valuable mental training than such subjects as analytical geometry is that the older authors, perhaps because they were a bit afraid of purely symbolic argument, tried constantly to keep real pictures and ideas before the minds of their readers. But even so our conviction of the truth of any but the simplest theorems of geometry depends chiefly on the symbolic argument, not on the realization in succession of the actuality of the relations and operations discussed in the course of the proof. This is perhaps sufficiently obvious in the higher branches of even Euclidian geometry, but it becomes absolutely indisputable when we reach such theorems as "Any two conics in one plane intersect in four points." Not only may some of these points be at an infinite distance, but some, or all, may be what is called, on the *lucus a non lucendo* principle, "imaginary", that is, they may be such that they cannot be imagined by anybody, much less actually drawn.

Accordingly I cannot admit that the theorems of geometry are established by induction at all. If they are interpreted in either of the first two ways I have described, they are only particular propositions, and the inference from them to a general proposition would no more yield a "mathematical certainty" in this case than in any other. And though the third way of looking at the proposition may be paraphrased into a form which appears general (*e.g.*, anything which may fairly be called "an isosceles triangle" may also be said "to have two equal angles"), it is really only a particular proposition about the words "isosceles triangle," and so on. Its wide applicability and usefulness depends on the fact that we can, and do, often find things which can fairly be called isosceles triangles, but it must be admitted that the assertion that, on any given occasion, we have found such a thing,—is not a mathematical certainty. If the triangle in question is an objective one, we can only say that it is probably, or approximately, isosceles, and though perhaps we may subjectively conceive perfectly isosceles triangles, and so regard the *pons asinorum* as a subjective necessary truth, it must be doubtful whether we could do so in the case of a more complex proposition such as Pascal's Theorem, and it is quite certain that we could not do so in the case of such theorems as that about the intersections of two conics.

It is to be hoped, therefore, that logicians will come to recognize the importance of symbolic reasoning, as mathematicians have already done. And when they do so we may hope for this further advantage, that they in turn will teach mathematicians and others not to confuse a purely symbolic with a real conclusion—not to assume that, because they have correctly proved a conclusion symbolically, that it therefore necessarily gives any information about real things, or even real concepts.

EDWARD T. DIXON

Trin. Coll., Cambs., October 22

#### Bell's Idea of a new Anatomy of the Brain

IN NATURE of October 27 the writer of the review of Mr Horsley's "Structure and Functions of the Brain," speaking of the rarity of the above book, states that he only knows of one copy in London, viz., that in the British Museum. It may be useful to some of your readers to know that there is a very interesting copy in the library of the Royal College of Surgeons. It is the presentation copy to Dr. Roget "from Mr C. Bell, 34, Soho Square," by Dr. Roget it was given to Lady Bell, who presented it to the Royal College of Surgeons through Mr Alexander Shaw.

Mr. Shaw has added in MS. a copy of the letter received from the printers fixing the original date of publication, and also the list of persons to whom presentation copies were sent. The letter and the list are both published in Mr. Shaw's reprint of the Tract in the *Journal of Anatomy*, vol. iii., 1869.

JAS. B. BAILEY,

October 27

Librarian Roy. Coll. Surgeons

#### Photographic Dry Plates.

IN reference to "Prevention's" note on Photographic Dry Plates, one cannot but agree with him that packets should be dated when issued from the factory.

I would venture, however, to suggest that good makers' plates do not deteriorate within a reasonable length of time.

As an illustration of my experience I may mention that in April this year I opened a box of plates ( $\frac{1}{2}$  plate Extra Rapid) which I bought in July 1886.

NO. 1201, VOL. 47]

I had carried them on a three months' tour in the Mediterranean in 1888 and had taken no special care of them since.

They proved in every way as good as new, both in sensitiveness, and perfection and evenness of film.

ARTHUR E. BROWN

#### THE GENUS SPHENOPHYLLUM

NOTWITHSTANDING the small size and comparative scarcity of the plants belonging to this Palæozoic genus, they have long attracted a rather unusual amount of attention. This has been partly due to their peculiar external forms, which suggested even to the earliest observers the idea of resemblances to the Marsileæ, but the interest they have excited has been further increased of late years by discoveries respecting the peculiar organizations of their stems. In 1822 Adolph Brongniart assigned to them the name of "Sphenophyllites," and in 1823 Sternberg figured some of them under the generic title of "Rotularia." Sternberg's figures appeared in his "Versuch einer geognostisch-Botanischen Darstellung der Flora der Vorwelt," which work is now best known through the French translation of it by Comte de Bray. To the first of his specimens figured (*loc. cit.*, tab. xxvi, figs. 4a and b), Sternberg gave the name of *Rotularia pusilla*, and the example so designated is very characteristic of the simpler type of the group, in which we have a somewhat branched stem, with verticils of wedge-shaped leaves at each node. A second form was figured on a later plate of the same work. It is interesting to note that Sternberg associated with these figures the observation, "Plantæ organisatione foliorum Marsileis, forma caulis Hippuri Maritimæ." The generic name thus given by this author represents the rotate arrangements of the leaves in each verticil, as the wedge-shaped contour of each separate leaf is further indicated by Brongniart's generic term, "Sphenophyllites." In 1820 Von Schlottheim had also included similar examples in his too comprehensive genus, "Palmacites."

In 1828 Brongniart published his classic "Prodrome d'une Histoire des Végétaux Fossiles," in which work we find the generic name of these plants changed to Sphenophyllum, which name they have retained to the present time. In this work Brongniart examines in some detail the probable affinities of these plants, which even in 1822 he inclined to regard as having some affinities with the Marsileæ. He defines them as having six, eight, ten, or twelve leaves in each nodal verticil, each leaf being wedge-shaped, sometimes entire, truncated at its apex, which is denticulate. In some others these leaves are bilobed, and in other species they are not only profoundly bifid, but each of these lobes is either divided into two, or their ends are lacinated. Lastly, in some cases the lobes become narrow and linear. Brongniart here compares these leaves with those of Ceratophyllum and Marsilea, concluding with the statement, "We cannot for the moment decide between these two relationships." At this date the fructification was wholly unknown.

In his introduction to the "Natural System of Botany," p. 37, Brongniart again reverts to the idea that Sphenophyllum had Marsileaceous affinities.

In 1831 the authors of the "Fossil Flora of Great Britain" commenced their publication of that work, and in one of its early numbers they figured and described under the name of *Sphenophyllum erosum* what appears to be identical with the first figure published by Sternberg. When discussing the relationships of this plant, Lindley and Hutton

\* These figures were preceded in 1799 by a still earlier one by Scheuchzer in his "Herbarium Diluvianum" (Coemans and Klok, "Monographie des Sphenophyllum d'Europe").

\*\* Die Petrefactenkunde auf ihrem jetzigen Standpunkte."

reject Brongniart's idea of its possible affinity to the *Marsilea*, inclining to the belief that it approached nearer to the *Coniferae*, and especially to *Salisburia*. This impression they retained when, at a later date, they described a second species of the same genus.

In his "*Tableau des Genres de Végétaux Fossiles*," published in 1849, Brongniart returns to the subject. He here calls attention to the readiness with which *Sphenophyllum* may be confounded with the genus *Asterophyllites*, which some forms of the former genus closely resemble, but he again repeats that the two can be distinguished by the fact that in the former genus the leaves never exceed ten in number, whilst their form is triangular with a truncated summit. He again dwells upon the fact that in some *Sphenophylla* the leaves become so deeply lobed, narrow, and linear, as to be easily mistaken for those of *Asterophyllites*. He now affirms that the fructification is closely related to that of *Asterophyllites*.

As to the affinities of *Sphenophyllum*, Brongniart now asks, "Does the plant combine the leaves of a *Marsilea* with the verticillate of an *Equisetum*, or is it a Gymnospermous *Phanerogam*, the leaves of which approach those of the *Ginkgo*?" He does not answer the question, but concludes that this cannot be done until the fructification of the plant is better understood.

In 1864 a monograph on the species of the genus was published by M. Eugene Coemans and M. J. Kickx, but the authors make no serious effort to solve the vexed question of the affinities of the genus.

We now enter upon a new stage in the history of the genus. In 1870, M. Renault presented an important memoir to the French Academy of Science, which, for the first time, threw light upon the internal organization, especially of the stems, of *Sphenophyllum*. He described two examples, one from Autun and the other from St. Etienne, both of which exhibited a structure wholly different from that of any plant previously known, recent or fossil. In the centre of each stem was a primary vascular bundle, the transverse section of which was a triangle with three concave sides and three prolonged, narrow, intermediate arms. This axial organ underwent no subsequent growth after its first formation. But it was invested by a secondary zone, which was deposited upon the primary triangle layer after layer like a secondary xylem, producing a circular axis, which enlarged as the plant advanced in age. But this secondary growth did not consist of layers of vessels, but of vertical columns of thick-walled cubical cells. The cortex also exhibited specially distinctive features. These discoveries made it clear that *Sphenophyllum* constituted, not only a very distinct genus, but a type of plant far removed from everything previously described.

It fell to my lot to make the next advances in our knowledge of this genus. In 1871 I described in the memoirs of the Literary and Philosophical Society of Manchester a new fructification, to which further reference will be made later on. In 1872 I obtained from the Oldham deposits some new stems which obviously belonged to the same type as those discovered by M. Renault, but from which they differed in important points of detail. These were described in my Memoir, Part V, published in the Philosophical Transactions for 1874. Transverse sections of these closely resembled in their dominant features M. Renault's corresponding ones, but with two differences. When my plants attained to a certain stage of their exogenous growth, a well-defined circular boundary marked a temporary arrest of that growth, but which started afresh from a zone of much smaller vessels (*loc. cit.* Pl. II., Figs. 11 and 12), that increased in size as the diameter of the axis increased, as they had previously done in the more internal series. Still greater and more important differences presented themselves in the longitudinal sections.

The zones of secondary or exogenously developed xylem, which in M. Renault's examples consisted solely of vertical columns of thick-walled, cubical cells, were composed, in mine, of true tracheidal vessels with reticulated (not with bordered pits) walls, presumably a higher stage of development. Another new and more advanced feature than characterise Renault's cells, seen best in tangential sections of this zone (*loc. cit.* Fig. 13), was the existence, between contiguous tracheids, of vertical, but interrupted, series of small cells, which I can only regard as rudimentary medullary rays. In the same memoir (*loc. cit.* Pl. IV.) a still more distinct form from the Burntisland deposits in Fifeshire was figured and described. M. Renault and Count Solms Laubach refuse to recognize a *Sphenophyllum* in this type, but they have not yet convinced me that I am in error on the point. The fact is that, though widely aberrant from the form described above, it scarcely differs more from that form than the latter does from M. Renault's examples.

But my Oldham specimens raised another debated question. When the Memoir V was published, all authorities agreed that the maximum number of true leaves in each verticil was ten or twelve, that, however deeply subdivided, their outline was a sphenoid one, and not linear, and that they were multinerved. But I am still convinced that in my specimens there were more than twenty such leaves, that they were linear in outline, and had a single median nerve. It followed that, continuing to accept the existing definitions of the genus *Sphenophyllum*, my plant was *Asterophylloïd* rather than *Sphenophylloïd*. I am now prepared to admit that it is a *Sphenophyllum*, but only on the condition that we alter our definitions of the latter genus, and admit the possibility that some of the forms may possess twenty or more undivided and linear leaves. The accumulating evidence that the foliage of at least some of the *Sphenophylla* was dimorphic makes the acceptance of my proposition a matter of necessity.

Yet more recent researches have revealed new and important facts connected with the history of these plants. I have already alluded to the new fructification which I described in 1871, and to which I gave the name of *Volkmannia Dawsoni*. M. Renault's memoir already noticed was laid before the French Academy in May 1870, and noticed in the *Comptes Rendus* of that date, but owing to accidents growing out of the Siege of Paris, it was not published until three years later. Meanwhile my memoir on *Volkmannia Dawsoni* was published, and a copy of it forwarded to M. Brongniart. After giving details of the structure of the strobilus I arrived at the conclusion that "it is the fruit either of *Asterophyllites* or of *Sphenophyllum*."

Two years later M. Renault's memoir of 1870 was combined with a second one on the same subject, and published. It contained a note by M. Brongniart, referring to my memoir of 1871, in which note he says, "This work agrees in many important points with the results obtained a year previously by M. Renault, though Mr. Williamson was unacquainted with the article in the *Comptes Rendus* of May 30, 1870. The fossil plant studied by Mr. Williamson, and named by him *Volkmannia Dawsoni*, doubtless differs, at least specifically, from that described by M. Renault, by the form of the central vascular bundle, and by the absence of the zones of quadrangular cells which surround it in the French specimens, cells which in consequence of the thickness of their walls would not be readily destroyed."

\* M. Brongniart has here failed to comprehend an important point. The cells, the absence of which he notices, really belonged to the secondary xylem of the older stem, which did not become developed in the youngest twigs. But it was only upon these twigs that the fructifications were formed, and of which they were but extensions. Hence their absence was merely a consequence of difference of age, and not a feature of specific value.

In 1890 I figured in my Memoir XVIII (Phil Trans 1890) a transverse section of what was obviously a stem of *Bowmanites Dawsoni*, in which the primary triangular axis of the strobilus was invested by a thick zone of the secondary xylem. So far as the arrangement of its tissues is concerned this stem is constructed on exactly the same plan as appears in M. Renault's and my own *Sphenophylla*. In describing it I further said, "We must unite *Sphenophyllum* with some forms of *Asterophyllites* in the same genus. It is equally clear that *Bowmanites*, though its peculiar fructification demonstrates that it constitutes a perfectly distinct genus, has strongly marked features of affinity in the structure of its stem to the *Sphenophylloïd* type."

The above reference to differences between the fructification of *Bowmanites* and of *Sphenophyllum* were based upon the minute description of the fruits of the latter plant, published by M. Renault ("Études sur le Ferrain Houiller de Commeny," pp 481-2). Those descriptions differ widely from what exists in my *Bowmanites*, but M. Renault distinctly identifies them with the fructification of *Sphenophyllum*. I obtained additional and important specimens of *Bowmanites* in 1890, which threw much new light upon its organization, and which were recorded in my Memoir XVIII (Phil Trans 1891).

In July last an important communication was laid before the Academy of Sciences by my friend M. Zeiller, the distinguished director of the Superior National School of Mines at Paris. In it he records his identification of a fructification of a *Sphenophyllum* of the type of *S. pusillum* of Sternberg and *S. crosus* of Lindley and Hutton, with my *Bowmanites Dawsoni*. If this determination is correct, and I see no reason for doubting that it is so, we now have some more definite facts than we have hitherto possessed, guiding us alike in identifying the true fructification of *Sphenophyllum* and in determining its position in the vegetable kingdom.

Before explaining M. Zeiller's observations more in detail, a few words explanatory of the structure of *Bowmanites* will make M. Zeiller's views more intelligible to the reader.

The accompanying diagram represents two nodes and

one internode from a vertical section of this fruit, with the sporangia and three sporangiophores *in situ*.

So far as external contours are concerned, it is indistinguishable from many of the true Calamarian forms of fructification. It is only when cut into sections that its characteristics can be discovered. Its central axis (a) has nodes (b) at short and regular intervals, and at each node is a verticil of from 16 to 20 sporophylls or fertile bracts (c). At their basal portions these bracts are coalesced into a lenticular disk (d), from the margin of which the thinner and narrowing bracts extend upwards,

overlapping from two to three internodes. From the upper surface of the disk numerous slender sporangiophores (e) spring, each one proceeding upwards and outwards, to become attached to the upper or distal extremity of a large oval sporangium (f). Each of these sporangiophores has running through it a small bundle of barred tracheids, which terminate at the point of attachment to the sporangium. Each tracheal bundle is a prolongation of one of a circle of similar ones that ascend from the central axis into the disks. These fructifications, besides being manifestly eusporangiate, are extremely characteristic of the plant, nothing identical with them having been observed by any of the authors who have investigated the Carboniferous strobili. After these illustrations I will allow M. Zeiller to explain his views in his own words. After referring to the details given in my Memoir XVIII, M. Zeiller says—

"L'aspect de ces sporanges, ainsi attachés au bout de ces pédicelles recourbés, est exactement, à part les dimensions moindres, celui de sporocarpes de *Marsilea*. L'analogie paraît du reste n'être pas purement superficielle, M. Williamson a reconnu en effet, dans le pédicelle de chaque sporange, un cordon vasculaire bien caractérisé, qui prouve qu'on n'a pas affaire là à une simple formation épidermique, comme pour les sporanges de Fougères ou de Lycopodées. Il faut, à ce qu'il semble, regarder ces pédicelles comme représentant des lobes ventraux des bractées, analogues au lobe fertile des frondes d'*Ophioglossées*, ou à ceux des *Marsiliacées*, seulement ils portent à leur extrémité non pas une série de sporanges comme chez les premières, ou plusieurs sores comme chez ces dernières, mais un sporange unique à paroi formée d'une seule assise de cellules."

"De cette constitution des épis du *Sphenocaulifolium* il report que, si les *Sphenophyllum* rappellent les Lycopodées par la structure de leur axe, ils s'en éloignent notablement par la disposition toute spéciale de leur appareil fructificateur, qui tend à les rapprocher plutôt des Rhizocarpacees, et qu'ils doivent donc bien décidément être considéré comme formant une classe distincte parmi les Cryptogames vasculaires." Agreeing thoroughly with these conclusions further comments are needless.

WM CRAWFORD WILLIAMSON

#### DENDRITIC FORMS.

THE curious appearances presented by certain native specimens of silica have been observed for so long, that it is somewhat surprising that so little is known about their real constitution and mode of formation.

Rock-crystal is frequently found to contain bubbles of liquid, usually either water, carbon dioxide, or petroleum, or crystals, such as scales of mica, forming aventurine, and fibres, such as asbestos, forming cat's-eye. More rarely, however, forms of apparently vegetable origin are seen, one of the most remarkable specimens is a prolate spheroid, about five inches long and four inches across, cut from a clear colourless rock-crystal, in which are embedded numerous fragments about the size of a large pea, presenting the exact appearance of club-moss.

Agate is frequently found with distinct coloured layers, either flat or distorted, and usually milk-white, red, brown, or black. It is then known as *onyx*.

More rarely, agates are found with markings like moss or foliage distributed through them, they are then known as moss-agates, or Mocha stones.

In 1814, Dr J. MacCulloch described some cryptogamic forms in the agates of Douglas (Geological Trans., 11,

<sup>1</sup> The species of *Sphenophyllum* to which M. Zeiller's strobili were attached.

<sup>2</sup> *Comptes Rendus des Séances de l'Académie des Sciences, Paris*, July 11, 1890.

iv, 398) It is stated that the Earl of Powys possesses an onyx containing the chrysalis of a moth

It seems to be generally assumed, without any strong evidence, that rock-crystal and agate have been formed from solution in water, possibly superheated, and that in such cases as those mentioned above, various crystalline or fibrous minerals and low forms of plant life have been inclosed during the process of solidification

Though this explanation is very possibly true in many cases, it does not account for all the appearances seen in moss-agates, and another possible mode of formation may be suggested by a brief account of some experiments made more than twenty years ago

Ordinary crystals of ferrous sulphate dissolve readily in cold water, but if they are placed in a dilute solution of an alkaline silicate, an entirely new series of phenomena are produced, which were first described by J. D. Heaton, M.D., in a paper "On certain Simulations of Vegetable Growths by Mineral Substances" (Brit. Assoc. Report, 1867, p. 83). On immersing crystals of ferrous sulphate in a solution of sodium silicate of the density 1.065, very beautiful arborizations will soon begin to shoot perpendicularly upwards, attaining the height of three or four inches in a few hours. In a weaker solution roots can be caused to shoot downwards from a suspended crystal. The fibres contain silica and iron (less the weaker the solution), they are brittle, and more dense than the liquid in which they are formed. Examined by the microscope, the ultimate ramifications are cylindrical, tapering tubes, the walls of which are granular, showing no sign of crystallization. The roots are more abrupt and occasionally club-shaped in their terminations. The growth is interstitial like that of organized living tissue. "Supposing such purely mineral substances to have been formed in bygone geological eras, and to have been accidentally fossilized in some primary or other ancient rock, they would very probably, when discovered by recent investigation, be pronounced to be an evidence of organized beings having existed contemporaneously with the formation of such rock."

In the following year a similar observation was made by Prof. W. C. Roberts-Austen (J. C. S., 1868, xxi, 274). A solution containing 49 per cent of silica, when allowed to gelatinize, and dried for two days over sulphuric acid, left a solid residue similar to opal from Zimapan, but containing 21.4 per cent of water. All the specimens of jelly dried in air contained dendritic forms, varying in size from 0.2 to 0.5 mm. When magnified 90 times they appeared as radiating fibres, when the power was increased to 700 times linear, each fibre resolved itself into a series of elongated beaded cells with clusters of circular cells at intervals. Mr. Slack indicated their remarkable analogy to common blue mould or mildew. The cells appeared to be hollow, and did not blacken with sulphuric acid.

A few years later I repeated Dr. Heaton's experiments, and made some additional ones, a brief account of which may induce some one with better means at his disposal to investigate an interesting and somewhat neglected subject.

If a crystal of copper sulphate be suspended in a solution of potassium silicate, which has been carefully neutralized and has a density of 1.065, in the course of a few minutes a hollow green column will be seen to run down from the crystal to the bottom of the beaker. Sodium silicate may be used instead of potassium silicate, but the appearance and rapidity of the growth is somewhat changed. The solution may be neutralized with hydrogen sulphate, chloride, or acetate, but hydrogen fluoride appears to prevent all growth. If the solution has a density less than 1.06, no growth occurs, and the crystals generally dissolve; the weaker the solution down to this limit the more rapid the growth. If the solution be stronger, the time required for the growth to com-

mence may be lengthened from minutes to many days. If the density be above 1.25, no growth takes place.

Copper sulphate gives the best results, but it may be replaced by ferrous, manganous, or nickel sulphate, with changes in the shape, and of course in the colour, of the growths. The growths take place most readily from a clean sharp crystal, and always from an angle or edge, an edge obtained by cleavage requires more time. Other salts besides the sulphates may be used, but do not act so rapidly, probably owing to less perfect crystallization of the specimens used.

In a neutral or very feebly alkaline solution the growths are comparatively rapid, and consist of long, branching, tapering fibres, not unlike the roots of a tree. They grow rather more rapidly downwards than upwards. If the solutions be decidedly alkaline, the growths are much slower, and consist of fine stalks with comparatively large lumps at the extremities.

The tubes seem to be composed of silica with a small proportion of the metal used, they differ much in colour, are more dense than the liquid in which they grow, and are insoluble in water or dilute acids. When magnified 100 times, the substance of the tube shows no appearance of crystalline form, but seems to consist of concretions of ovoid granules. In this particular it differs from the substance of lead or silver trees, and from the curious fibres of potassium iodide, and chloride described by Mr. Warington (J. C. S., v, 136, viii, 31).

It is generally assumed that the formation of onyx is due to the successive deposition of layers of silica coloured by different substances, but the following experiment suggests another possible method of formation, especially when the extreme permeability of gelatinous silica by liquids is remembered. So readily are even the hardest agates permeated by hot aqueous solutions of salts, that "staining" is a common commercial process.

A little too much sulphuric acid was accidentally added to a moderately strong solution of potassium silicate in which some crystals of copper sulphate were lying. The copper sulphate dissolved, and the solution set to a uniform blue jelly. After standing for about a week, the blue colour at the top of the jelly had separated into a series of thin parallel coloured plates, leaving the jelly between them colourless. This curious separation of the colouring-matter gradually proceeded downwards, and reached the bottom of the precipitating glass in about a month. The jelly gradually shrank, dried, and hardened, forming fragments consisting of blue bands in a white mass.

SYDNEY LUPTON

## NOTES

THERE will be a memorial celebration for A. W. von Hofmann on November 12, arranged by the Deutsche Chemische Gesellschaft, at Berlin on the 25th anniversary of its foundation. The Empress Frederick and many German and foreign celebrities have been invited to be present. The proceedings, which will take place at the Berlin Town Hall, will include speeches on the history of the Society and on Hofmann, a review of progress in chemical science by Hr. Wislicenus, and choral music, performed by the members of the cathedral choir.

WE regret to have to record the death of Mr. Robert Grant, F.R.S., Professor of Practical Astronomy at the University of Glasgow. He died at Grantown-on-Spey, his native place, at the age of seventy-eight.

THE death of Dr. Löwenherz, director of the Imperial Physical Institute, Berlin, has been announced. He died at Berlin on Sunday last.

PROF. VINCOW has been appointed an honorary member of the Imperial Russian Natural Philosophy Society.

AN international ethnographical exhibition is to be held next year in St Petersburg. It will be organized by the Russian Geographical Society.

THE American Microscopical Society offers prizes for the encouragement of microscopical research, two of the value of 50 dollars each, and two of the value of 25 dollars each, for the best papers which shall give the results of an original investigation made with the microscope, and relating to animal and plant life respectively, also two of the value of 30 and 15 dollars respectively for the best six photomicrographs in some subject of animal or vegetable histology, and two of the same value for the best collections of six mounted slides illustrating some one biological subject.

IN a letter to the *Times* on scientific titles and their abuse Prof Tilden has opened a subject of considerable interest to men of science. It is well known that the letters indicating membership of a society are sometimes used by persons who have no right to use them, and Prof Tilden notes that an effort is to be made to deal with this evil by getting a Bill before Parliament "for the purpose of securing to the respective societies the copyright of these letters." This, however, is a comparatively unimportant aspect of the question. The real difficulty is that membership of scientific societies is frequently "represented in courts of law or by candidates for public appointments as evidence of professional trustworthiness," whereas in very many cases it does not at all necessarily imply any extensive or accurate knowledge of the subjects in which the societies are especially interested. "Fellowship of the Royal Society indicated by the letters F R S," says Prof Tilden, "is a real distinction which is justly prized. But what is the public to understand regarding such alliterations as F B S, F C S, F E S, F G S, F L S, F S S, F Z S, and of F S A, M R I, F R A S, F R M S, F R G S, F R S E, &c? With the exception of one or two of the societies represented here, admission is to be gained by almost any one who is willing to pay the customary contribution to the funds of the society, and who can get two or more members of the society to testify to his fitness for admission, which generally means respectability and a profession of interest in the subject, the cultivation of which is the object of the society." He adds that if the public knew all about the societies no harm would arise, but "judges and barristers, and county councillors and town councillors cannot be expected to have this knowledge." Prof Tilden thinks that "the only chance for a better state of things is for every member of these societies who respects himself to abandon the use of these unmeaning letters altogether", but he fears that there is very little prospect of such a general reform while "an Institute having for its president no less a person than the Heir Apparent to the throne condescends to bait its advertisements for subscribers with the offer of more letters." The *Times*, discussing the subject in a leading article, expresses the opinion that in the main "we must trust, imperfect though the security is, to the ability of grown-up men and women to protect themselves against a form of deception which has most hold over those who themselves covet the meaningless letters to which they blindly pin their faith."

THE weather during the past week has been characterized by a marked increase of temperature and excessive rainfall, accompanied by strong southerly winds and gales. Between Wednesday the 26th and Friday the 28th October, the temperature in parts of England increased upwards of 30°, while the air became very humid and unpleasant. The continuance of comparatively high temperature, during which the thermometer reached 60° in the central and southern parts of the kingdom, was due to the track of the depressions, causing a continual indraught of warm air from off the Atlantic. On Thursday the 27th ult, about 1½

inch of rain was measured in the West of Ireland, and heavy falls occurred on the following days in the Midland counties. A further downpour, amounting to 1½ inch in the Channel Islands, and to 1.3 inch in London, occurred on Sunday night, and the amount which has fallen on the east coast of Norfolk during the month of October is about equal to three times the average. During the first part of the present week, the disturbance which caused the heavy rainfall passed away, and a small area of high pressure temporarily advanced over the United Kingdom from the Atlantic, while the temperature fell several degrees, with mist or fog in places, but conditions were very unsettled, and a change of wind to the south-eastward in Ireland gave indications of probable further disturbances. During the week ended the 29th ultimo, the amount of bright sunshine exceeded the mean in nearly all districts.

THE Meteorological Council have recently issued a summary of the *Weekly Weather Report* for the quarter ending September 1892 which shows the rainfall and mean temperature in each district for each similar quarter for the twenty-seven years 1866-92, grouped in five yearly averages, and also the means for individual years from 1881. The average rainfall of the quarter for the whole of the British Islands was 10.2 inches, or only 0.7 inch in excess of the mean for the whole period. This result is almost entirely due to an excess in the grazing or western districts, amounting to 1.5 inch, while in the wheat producing or eastern districts the fall for the quarter is slightly below the mean. The temperature for the quarter has been below the mean generally, for the whole of the country the deficiency amounted to 1° 8, and was 1° 7 in the grazing districts and 1° 9 in the wheat-producing districts. Similar returns show that the excess of rainfall amounted to 1.5 inch in the same quarter of 1891, prior to which there had been a series of seven dry quarters, while the temperature has been uniformly below the mean for six corresponding quarters. The coldest quarter was in 1888, when the deficiency amounted to 2° 5, this being, in fact, the coldest corresponding quarter during the last twenty seven years.

THE late Mr George Grote, the historian of Greece, expressed in writing, eight years before his death, a desire that after his decease his cranium should be opened and his brain weighed and examined. The task was undertaken by the late Prof John Marshall, and the results of his observations are set forth in a full report printed in the current number of the *Journal of Anatomy and Physiology*. The entire encephalon was somewhat above the average in size, if compared with the adult male brain at all ages. If allowance be made for the effects of senile wasting, it must be regarded as a rather large brain, but not as an actually or especially large one. There can be no doubt, however, that it was, at death, further diminished in size and weight through the effects of disease, as shown by its marked deviation from the ordinary ratio as compared with the body-weight. As tested by the standard of macrocephaly adopted by Welcker, its utmost allowable weight was below that standard, and as contrasted with the encephala of certain other eminent men, it would find its place about one-third up from the lowest end of the list. The general form of the cranium was rather or nearly brachycephalic, but it was decidedly higher than usual. The cerebrum itself was, in accordance with the shape of the cranium, short, broad, and deep. The cerebral convolutions were very massive, being not only broad and deep, but well folded, and marked with secondary sulci. This condition was observable all over the cerebrum, but chiefly remarkable in the frontal and parietal regions. Studied in reference to Dr Ferrier's researches into the localization of function in the brain, the relative size of certain convolutions or groups of convolutions suggested some reflections as to individual peculiarities, but these reflections did not seem to Prof Marshall

to be quite trustworthy. From the size and richness of the convolutions, the sufficiency of the grey matter both on the surface and in the interior of the hemispheres, and from the remarkable number of the white fibres, especially of the transverse commissural ones, the brain of Mr Grote is pronounced to have been of very perfect and high organization.

THE method of cleaning mercury adopted at the Physikalisch-technische Reichsanstalt at Berlin is described in the *Zeitschrift für Instrumentenkunde*. The raw material is brought in iron bottles from Idria. It is filtered and dried, and twice distilled in a vacuum to get rid of the heavy metals. Great care is taken to eliminate fatty vapours derived from greased valves and cocks, which is accomplished by means of a mercury pump working without a stopcock. Finally, the electro-positive metals, such as zinc and the alkalis, are separated by electrolysis. The mercury is precipitated from a solution of mercurous nitrate obtained by the action of nitric acid on excess of mercury. The solution, together with the impure mercury acting as an anode, is contained in an outside glass vessel, into which a current from a Gulcher thermopile is conducted by an insulated platinum rod. The cathode rod dips into an interior shallow glass vessel, in which the pure mercury is collected. On careful analysis it was found that no perceptible non-volatile residue was left by 200 grammes of the purified metal. Thus the mercury is well fit for use in standard barometers and resistances.

WITH regard to the revival of animals after exposure to great cold, Herr Kochs (in the *Biologisches Centralblatt*) points out two things which retard formation of ice in the animal body. First, the body does not contain pure water, but salt and albumen solutions, which only freeze under zero C. Then capillarity and adhesion hinder freezing. Herr Kochs states that water in a glass tube of 0.3 to 0.4 mm. diameter may be cooled to  $-7^{\circ}$  and even  $-10^{\circ}$  C. without freezing. With a diameter of only 0.1 to 0.2 mm. the water is not frozen, even though the end of the tube be put in freezing liquid. Thin liquid sheets between two glass plates behave in the same way. If a salt solution freezes, the salts are excluded, and pure water, in freezing, gets rid of its absorbed gas. Fresh blood, according to the author's experiments, freezes only after being strongly cooled to  $-15^{\circ}$  C., and after complete elimination of gases and salts. The blood corpuscles are dissolved and the blood loses colour. The same elimination doubtless occurs in freezing of protoplasm. Experiments cited to show the possibility of "anabiosis" may probably be explained by the decomposition process not having gone so far as to bring life completely to a standstill. Similar results were obtained in experiments on drying of seeds and various animals. It was shown with what tenacity many animals, under most unfavourable circumstances, retain the moisture necessary to life.

THE very destructive American disease of the vine known as the "Black rot" has, for some years past, made its appearance in Europe, and its life-history has now been thoroughly investigated by Viala, Rathay, and others. The ravages of the disease have been traced to a parasitic fungus, *Lasdadia Bidwellii*, the mycelium of which develops in the interior of the organ attacked, chiefly the young branches and berries, and produces sporogones and pycnids in the course of the summer. It is especially by the pycnospores that the fungus is disseminated. Towards the end of the period of vegetation sclerotes are formed, usually within the pycnids, and the conidiophores spring from these. Peritheces are also formed in May and June on the fallen and infected berries of the previous year. Until recently the ravages of this pest in Europe were confined to the French vineyards, but it has recently been detected in Austria and in Italy. The most effectual remedy for it is salts of copper.

THE results obtained from the botanical work done at the various experiment stations in the United States will in future be published in the form of an "Experiment Station Record," issued by the Department of Agriculture, under the editorship of Mr. Walter H. Evans.

ANGLO INDIAN papers record the presentation of an interesting "piece of architecture" to the Madras Central Museum by Lord Wenlock. It is a hornets' nest, belonging probably to the species *Vespa cincta*. It is conical in shape, and is constructed of a material resembling rough paper or cardboard composed of woody portions of plants gummed up by the insects, and brought into the condition of paste by means of a viscid salivary secretion. The combs are placed in tiers and attached to each other by small columns of the same paper like material of which the nest is composed. It is two feet in height, and about the same in circumference at the base. It was obtained in the course of one of His Excellency's tours.

M. DE NADAILLAC, in the current number of *La Nature*, discusses the significance of some of the facts which have been brought to light by the recent excavations of mounds in the Ohio Valley. The mound builders knew how to construct earth fortifications, which were of considerable extent and always remarkably adapted to the sites chosen. They buried their dead under tumuli of astonishing dimensions. Copper was the only metal they could work, and they undertook long journeys in search of it. Their weapons and implements were of stone. They made vases of pottery, and were able to produce representations of the human figure and of animals, both by sculpturing them in stone and by modelling them in clay. At least in some districts they were sedentary, and, like all sedentary populations, they had to obtain the means of subsistence in part by cultivation of the soil. They were often engaged in fighting, and numerous burials in which the bodies are crowded together bear witness to the fury of their struggles. Whence did they come and who are their descendants? M. de Nadaillac thinks that these questions can never be definitely answered unless investigators discover some traces of the language of the mound-builders.

AN interesting and valuable paper on the association of shipping disasters with colour-blind and defective far-sighted sailors, read by Dr. T. H. Bickerton before the section of Ophthalmology at the last annual meeting of the British Medical Association, has been reprinted for the author from the *British Medical Journal*. Dr. Bickerton takes anything but a hopeful view of the prospects of legislation on this important question. He greatly fears that "many a shipping disaster will occur before the Royal Society's suggestions become part of the law of the land." Accordingly he urges all who interest themselves in the subject to abate not a tittle of their endeavours. "There are none," he says, "so difficult to convince as those who will not believe, and the men who have had the framing of the rules of the road at sea are the very men who hitherto have turned from all suggestions on the eyesight question with contempt. True it is that their language, judged from examples to be found in the *Nautical Magazine*, is becoming moderate, and even polite, but they lack knowledge of this subject, and they will still require our best attention." Meanwhile, Dr. Bickerton presses on the attention of the public the following facts.—that 4 per cent. of the whole male population are colour blind, that about 8 per cent. more have marked impairment of sight from refractive errors; that there is no official test whatever as to a sailor's eyesight; that a man may be the subject of any of the forms of eye disease, may have any degree of blindness, or may be so short-sighted as to be unable to see distinctly more than a few inches in front of his nose, and yet be at perfect liberty to be a sailor and to become an officer; and that, although there is a

compulsory colour examination (in many cases a most inefficient one) to be passed before a sailor can become an officer, there is no check to a colour blind man being a sailor, or to his remaining one to his life's end

THE Rev T A Marshall describes in the November number of the *Entomologist's Monthly Magazine* a new genus and species of Belytidae from New Zealand. The paper is accompanied by representations of two insects in fine condition. Mr Marshall abstains from giving tedious details, as the figures will, he believes, convey a better idea of these creatures than many words, and he thinks they will now be unmistakable, at least until other species of the same genus shall be discovered. He has not taken any characters from the under-side, the specimens being carded, hence the oral organs could not be described, but they may be pretty safely assumed to resemble those of *Belyta*, *Anactata*, &c., and their details would have been of little value.

A CORRESPONDENT of the New York journal *Electricity*, writing from Paris, describes some electrical peculiarities which he has seen in a cat. This cat, called Michon, is a half wild animal, and dislikes handling. It belongs to the household of Dame Gais, whose residence on the Carnier Mount, near Monte Carlo, looks directly down on the noted gambling casino and its botanical reservation. On some of the cold and very dry nights common to Monte Carlo in the winter, Michon, while in the dark, is quite a spectacle. Every movement of its body sends off hundreds of minute bluish sparks, something like those thrown off by ill-adjusted brushes, though not so pronounced in colour. They make a noise on a small scale, like the crackling of burning furze. Stroking the cat increases the sparking, and ruffling its fur the reverse way produces a miniature pyrotechnic display quite remarkable. The cat itself does not seem to mind the sparking, but, like all cats, dislikes to have its fur rubbed in a wrong direction. The writer has never seen the electric element so abundant in a cat, and many who have seen the convulsions that have given notoriety to Michon, confirm him in the opinion that the cat is an electrical curiosity.

A USEFUL account of "Biological Teaching in the Colleges of the United States," by Prof John A Campbell, of the University of Georgia, has been issued by the United States Bureau of Education. The writer's object is to present the actual extent and scope of the biological courses offered by the colleges of the United States, together with the methods of teaching employed. He also aims at presenting as fully as possible an account of the equipment and facilities for teaching which the various colleges possess. The statements he makes are therefore based largely upon the printed accounts found in the college catalogues, supplemented in many cases by letters containing additional information. These have usually been re-written, but where they are in suitable form they are quoted directly. Prof Campbell notes that many of the colleges announce more in their catalogues than they can possibly do thoroughly with the teaching force employed. This is often perfectly apparent, but in more than one letter received the statement has been made that certain courses have no existence save on paper. Prof Campbell, however, thinks that it is worth while to record the views of the professors in charge in regard to the nature and aims of such work, and the ideals towards which they are striving.

THE "Treatise on Hygiene and Public Health," edited by Dr. T. Stevenson and Mr. Shirley Murphy, and reviewed in NATURE last week, is published by Messrs. J. and A. Churchill.

NO. 1201, VOL. 47]

MESSRS J AND A. CHURCHILL are publishing a second edition, revised and enlarged, of "Commercial Organic Analysis," by Alfred H Allen. The second part of the third volume has just appeared. The third part of the same volume will be issued as soon as possible, and will complete the work. In the second part he has sought to describe fully and accurately such of the organic bases as have any practical interest, and to give trustworthy information as to their sources.

THE new number of *Natural Science* includes articles on the evolution of consciousness, by C Lloyd Morgan; primæval man, a palæolithic floor near Dunstable, by W G Smith; the evolution of sharks' teeth, by A S Woodward; the walk of arthropods, by G H Carpenter; the falling of leaves, by A R Rendle; and Norwich Castle as a museum, by H Woodward.

A REVISED edition of "London Birds and London Insects," by Mr T Digby Pigott, has been issued by Mr H Porter. Along with the essays on these subjects have been printed several other bright and attractive sketches.

AN elaborate index to the genera and species described in the "Palæontologia Indica," up to the year 1891, by W Theobald, has just been issued. It is included among the Memoirs of the Geological Survey of India. Mr Theobald has also prepared "Contents and Index of the Memoirs of the Geological Survey of India, 1859 to 1883."

A SECOND edition of Dr F H Hatch's "Text-book of Petrology" has been issued by Messrs. Swan Sonnenschein and Co. The author explains that he has taken advantage of this opportunity to revise the book thoroughly, while largely increasing its scope.

THE Society for Promoting Christian Knowledge has published a second edition of Klein's "Star Atlas." Mr E. McClure, the translator of Dr Klein's explanatory text, has sought to bring up to date the German writer's descriptions of the more interesting fixed stars, star clusters, and nebulae.

MESSRS ROBERT GRANT AND SON, Edinburgh, and Messrs Williams and Norgate, London, have issued Parts II. and III of Vol XXXVI of the Transactions of the Royal Society of Edinburgh. The following are the subjects of some of the papers:—the foundations of the kinetic theory of gases (IV), by Prof Tait; the solid and liquid particles in clouds, by J. Aitken; the development of the carapace of the chelonians, by J B Haycraft; the composition of oceanic and littoral manganese nodules, by J Y Buchanan; the winds of Ben Nevis, by R T Omond and A Rankin; and the Clyde sea area, by H R Mill.

THE University College of Wales, Aberystwith, has issued its calendar for its twenty-first session, 1892-3.

THE City and Guilds of London Institute has issued its programme of technological examinations for the session 1892-93.

MESSRS GEORGE PHILIP AND SON announce that a work on "British New Guinea," by Mr J P. Thomson, Hon Sec. to the Brisbane Branch of the Royal Geographical Society of Australasia, is almost ready for publication. An appendix will contain contributions to the geology, fauna, flora, &c., by Sir William Macgregor, K C M G, Baron Ferdinand von Mueller, Professor Liversidge, F R S, and others. The proof sheets have been revised by Dr H Robert Mill and Dr. Bowdler Sharpe.

ANOTHER and apparently much more convenient mode of preparing glycol aldehyde,  $\text{CH}_2\text{OH}\cdot\text{CHO}$ , the first member of the series of aldehyde-alcohols, is described in the current number of the *Berichte*, by Drs. Marchwald and Ellinger, of

Berlin It may be remembered that in our note of a fortnight ago (vol 46, p 596), it was announced that Prof Emil Fischer and Dr Landsteiner had succeeded for the first time in preparing this interesting substance in a state of tolerable purity by a reaction analogous to that of barium hydrate upon acrolein dibromide, the reaction which yielded the first synthetical glucose. They first prepared the mono-bromine derivative of common aldehyde,  $\text{C}_2\text{H}_4\text{BrCHO}$ , and subsequently reacted upon this new substance, a liquid possessing an intolerably sharp odour, with baryta water. After removal of the baryta by sulphuric acid, and the hydrobromic and sulphuric acids by means of carbonate of lead, a liquid was obtained which possessed the properties of a dilute solution of glycol aldehyde. Some time ago Pinner obtained a derivative of this aldehyde which bore the same relation to glycol aldehyde, that the compound known as acetal,

$\text{CH}_3\text{CH} \begin{matrix} \diagup \text{OC}_2\text{H}_5 \\ \diagdown \text{OC}_2\text{H}_5 \end{matrix}$ , bears to common aldehyde. This substance,

glycol acetal,  $\text{C}_2\text{H}_5\text{OH} \begin{matrix} \diagup \text{OC}_2\text{H}_5 \\ \diagdown \text{OC}_2\text{H}_5 \end{matrix}$ , Pinner attempted to de-

compose, by the action of mineral acids, into ethyl alcohol and glycol aldehyde. The attempt, however, did not succeed, inasmuch as the decomposition went further, any glycol aldehyde that may have been formed during the first stage of the reaction being subsequently broken up. Drs Marckwald and Ellinger now find that the reaction succeeds admirably, provided the acid employed is extremely dilute, and as glycol acetal is a substance very easily prepared, they show that the reaction affords a very convenient and advantageous method of preparing large quantities of glycol aldehyde. The glycol acetal is added to an equal volume of water acidified with only a few drops of sulphuric acid. The liquid is then heated to boiling. After a short time the two liquids mix, and the reaction is completed when upon the addition of water to a few drops of it no separation of oil occurs. Upon distilling the liquid product, alcohol first passes over, then there distils a mixture of water and glycol aldehyde until decomposition of the residue commences. Glycol aldehyde, as thus obtained in a tolerably concentrated form, appears to be much more volatile in steam than was observed by Prof Fischer and Dr Landsteiner, in case of their more dilute solutions. From a few cubic centimetres of the distillate Drs. Marckwald and Ellinger obtained a very considerable quantity of Prof Fischer's phenylhydrazine compound, and confirm in every detail the other properties of glycol aldehyde described in our previous note above referred to. The chemistry of this first member of the series which includes the sugars is now, therefore, fairly complete, and the difficulties in the way of its preparation surmounted.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♂) from India, presented by Mr Pascoe Grenfell, F.Z.S., a Philantomba Antelope (*Cephalophus maxwelli*) from West Africa, three Gambian Pouched Rats (*Cricetomys gambianus*) from West Africa, a Ground Rat (*Aulacodus rundermanni*) from West Africa, and a White-faced Tree Duck (*Dendrocygna viduata*) from West Africa, presented by Mr. C. B. Mitford; a Martial Hawk-Eagle (*Spizaetus bellicosus*) from South Africa, presented by Mr. T. White, two Weaver Birds (*Hyphantornis sp. inc.*) from South Africa, presented by Mr. A. W. Arrow-smith, two Silver Pheasants (*Euplocamus nycthemerus* ♂ & ♀) from China, presented by Mr. E. Mitchener, a Common Chameleon (*Chamaeleon vulgaris*) from North Africa, presented by Miss Kate Higgins, a Thick-tailed Opossum (*Didelphys crassicaudata*) from South America, a Garden's Night-Heron (*Nycticorax gardeni*); and two Saracura Rails (*Aramides saracura*) from South America, purchased, and a Squirrel Monkey (*Chrysothrix sciurea*) from Guiana, deposited

## OUR ASTRONOMICAL COLUMN.

COMET BROOKS (AUGUST 28).—The following ephemeris, which we take from *Astronomische Nachrichten*, No. 3125, gives the apparent Right Ascensions and Declinations of Comet Brooks, which is brightening very rapidly.—

### 12h Berlin M T

This comet will still be found to form approximately an equilateral triangle with  $\alpha$  Aquilæ and  $\beta$  Delphini on November 5.

TABULAR HISTORY OF ASTRONOMY TO THE YEAR 1500 A.D.—Dr Felix Muller, of Berlin, has just completed a small volume entitled "Zeittafeln zur Geschichte der Mathematik, Physik und Astronomie bis zum Jahre 1500," which will be welcomed by all interested in the very early history of the exact sciences. The book is arranged chronologically and gives a short account of the chief workers in these branches of science up to the year 1500. At the end of each reference a list of the literature likely to be needed is added. The work is published by Messrs. B. G. Teubner, Leipzig.

A LARGE TELESCOPE.—The Americans seem to have made up their minds to be the possessors of the largest telescopes in existence, for in spite of their owning the great Lick Refractor (36-inch) we hear now that the University of Chicago are about to have "the largest and most powerful telescope in the world." This instrument will be the gift of Mr. Charles Jerkes, and will cost half a million dollars. The object glass will have a diameter of 45 inches and will be made by Messrs. Alvan Clark, of Cambridge, Mass.

THE ATMOSPHERES OF PLANETS.—Of all the planets that revolve round our sun, Jupiter affords the most suitable of them for the study of atmospheric circulation. That his circulation will not be exactly like ours will be at once evident, for not only does the sun pour his rays on his vast surface, but he possesses himself heat, as is suggested by the rapid changes which these cloud masses undergo. A recent hypothesis, explaining the various movements in this planet's atmosphere, has been put forward by Mr. Marsden Manson, in the fifth number (vol ix.) of the "Transactions of the Technical Society of the Pacific Coast," San Francisco. The chief element which produces these movements is the action of the sun, and it is on this reasoning that he attempts to unravel the laws underlying the circulation in Jupiter's atmosphere. In this pamphlet he first brings together some of the facts relating to our own wind system, which are generally conceded, together with the important results that were gathered from the path taken by the Krakatoa

dust-cloud. The spots observed on Jupiter's surface are next dealt with, a table of their rotation periods and latitudes being included. From the latter he deduces that the mean periods of rotation of matter in the following latitudes are:—

Lat.		h	m	s
12° N	from 17 N	Temp	spots	9 55 36.49
4° N	„ 5 N	Equat	„	9 50 40.06
8° S	„ 21 S	Equat	„	9 50 22.4
30° S	„ 3 spots			9 55 17.1

In treating of the spots themselves, he suggests that those which are of a white appearance are gyrating uprushes of warm air from the lower regions, while the dark ones are simply descending columns of cool air, "the two forming parts of the system of vertical circulation." The red spot, he suggests, is caused by a local escape of internal heat, the repellent force it appears to possess being due to the "spreading of the heated currents as they rise." He explains the retardation and acceleration of its period of revolution by the increasing force of the west winds, brought about by the exposure of the southern hemisphere during Jupiter's half-year (5.93 of our years), in this way the spot is sometimes situated over and sometimes to one side of the source of heat underneath. The author also deals with other spots in a similar manner.

### GEOGRAPHICAL NOTES

MR SVEN HEDIN'S account of his ascent of Mount Demavend is published in the last number of the *Verhandlungen* of the Berlin Geographical Society. Demavend is a volcanic peak rising abruptly from the sedimentary rocks of the parallel Libarz chains. Starting from the village of Kanah on the south-eastern slope with two guides, on July 10, 1890, Hedlin reached the summit on the afternoon of the next day. On the summit a large elliptical crater was found, the edges of which were strewn with blocks of porphyritic lava and sulphur. After discussing the aneroid and boiling point observations, Mr Hedlin arrived at 5465 metres (17,930 feet) as the height of the summit. This is lower than any of twelve earlier estimates which are cited, the highest of them being 6559 metres.

THE Italian possession of Eritrea on the coast of the Red Sea gives some promise of becoming useful agriculturally. Several small settlements of Italians on the plateau have succeeded in growing large crops of wheat and barley, and only the unsettled state of the surrounding natives threatens the prosperity of the farmers. The districts of Oculé Cusai and Guro are already fully cultivated, and Sarac, as yet almost unoccupied, has fertile land and plenty of room for colonists. The Italians are able to work in climatic conditions which would rapidly exhaust the natives of northern Europe.

THE general summary of Mr Conway's expedition in the Karakoram range (telegraphed from India (p. 525) has now been supplemented by a full narrative, written to the secretaries of the Royal Geographical Society from a camp on the Baltoro Glacier on August 29, with a postscript added at Skardo, on the way to Leh, on September 12. The difficulties of the preliminary journey were very great, not the least being the fording of several swollen glacier streams by a party numbering four Europeans, four sepoys, seventy coolies, an indefinite number of followers, and flocks of goats and sheep. The moraines on the Baltoro glacier were of almost incredible extent, for two thirds of its entire length the ice is entirely concealed by stones, except where crevasses or lakes occur, and the irregularity of the surface made travelling extremely slow. Mr Conway limits the name of Godwin-Austen to the highest peak of "K<sub>2</sub>," giving to the whole mountain the somewhat cumbersome title of the Watch Tower of India. One branch of the Baltoro Glacier results from the union of seven glaciers from this mass; the larger branch descends from the snow swathed, throne shaped mountain, hitherto unmapped, for which the auriferous quartz found in its rocks suggested the name of The Golden Throne. This was fixed upon as the goal to be attained. The first attempt landed the Europeans and Ghoorkas, who made excellent climbers, on Crystal Peak, 20,000 feet in elevation, a peak as hard to climb as the Matter horn, and isolated from the surrounding higher summits. No inconvenience was felt from the rarity of the air, and the party remained on the summit for an hour and a quarter. In the grand attempt on the Golden Throne serious difficulty was en-

countered from the terrible extremes of heat and cold. The last few thousand feet proved very exhausting, one of the Ghoorkas had to be left behind, suffering from mountain sickness. Every step had to be cut in hard ice. Finally the summit was reached at an elevation of 23,000 feet, but the Golden Throne stood revealed much higher, and separated by a deep depression. From the summit of Pioneer Peak, probably the highest yet reached by man, a series of photographic views was obtained and prismatic compass bearings taken to the surrounding features. As long as the party were at rest they felt no discomfort, but the sphygmograph showed that the heart's action was very laboured. A stay of an hour and a quarter was made on the summit, the view from which baffled description. The descent was safely made, but fatigue and bad weather stopped further exploration.

### THE INSTITUTION OF MECHANICAL ENGINEERS

ON the evenings of Wednesday and Thursday of last week, the 26th and 27th ult., an ordinary general meeting of the Institution of Mechanical Engineers was held in the theatre of the Institution of Civil Engineers, by permission of the council of the latter Society. The President, Dr William Anderson, occupied the chair during the proceedings.

There were two papers on the agenda. The first was the report of the Institution's committee appointed to enquire into the value of the steam jacket. Mr Henry Davey is the chairman of this committee, and he had prepared the report, which is a bare record of facts without comment, and in this respect is, we think, defective. Numberless experiments have been made in time past as to the value of the steam jacket, and those now added by the labours of the committee do not largely differ from many that have gone before. We take it that the general opinion of competent engineers is that an advantage in efficiency is to be obtained by jacketing engine cylinders in an efficient manner, and cases in which the jacket has not been proved efficient are those in which it has not been properly applied. What was wanted, therefore, was guidance as to the proper method of application, and it is significant that the most help in this direction came, during the discussion, from those who were not members of the committee. Timidity in expressing opinion will be excusably construed as indicating something of incompetence, and if the members are not capable of expressing opinion they are not suitable persons to form a research committee of an important institution. We frame our remarks hypothetically, because, with such names as Unwin, Bryan Donkin, and Mair-Rumley on the title page, there can be no doubt that the power to afford guidance was present, and for this reason the decision to give only bare fact is the more to be regretted. The general conclusion to be drawn from the experiments, as quoted, is that "the expenditure of a quantity of steam in an efficient jacket produces a saving of a greater quantity in the cylinder." It does not follow from this that the jacket is always desirable, as the saving may be so small as not to justify the additional complication and increased outlay at first cost. That, however, is a matter upon which steam users must themselves decide upon a commercial basis, and is, of course, outside the province of the committee, but what would have been valued would have been some critical remarks giving guidance as to what goes to constitute the "efficient jacket," what fresh engineering practice is opened up by the use of the efficient-jacket, and under what conditions it may be most effectually applied.

The first series of experiments quoted were carried out by Mr J. G. Mair-Rumley, of the firm of James Simpson and Co., of Fimlico, upon a compound jet condensing beam pumping-engine. The diameters of the cylinders are 29 inches and 47.5 inches, with strokes of 65 in. and 96 inches respectively. Only the body of each cylinder is jacketed, the steam being supplied direct from the boiler at a pressure of 49 lbs. per square inch above atmosphere. Experiments were made both with and without steam in the jackets. The total feed water per indicated horse power per hour when the jackets were not in use was 18.20 lbs., with the jackets in use the corresponding figures were 16.64 lbs., thus showing a percentage of less steam used due to the jackets of 8.6. The quantity of jacket water condensed was 1.20 lbs. per I.H.P. per hour. The boiler pressure here was not high, 49.7 lbs. without and 49 lbs. with jackets.

The number of revolutions were also low, 14.8 without jackets and 15.78 with jackets. This was evidently an engine which should pay for jacketing. We next come to an experiment of a different nature, carried out by Mr. Davey and Mr. W. B. Bryan. The engine is triple expansion surface-condensing engine of the inverted direct acting marine type, and is placed in the Waltham Abbey pumping station of the East London Water Works. The cylinders were 18", 30.5", and 51" in diameter, by 36 inches stroke. There is a Meyer expansion valve to the high pressure cylinder, by means of which the speed of the engine was regulated during the experiment. The bodies and both ends of all three cylinders are steam-jacketed. The jacket steam of the high pressure cylinder is at full boiler pressure, but the other two cylinders have the pressure reduced to a little above that of their steam chests by means of reducing valves. Each cylinder is therefore jacketed with steam a little above its own initial pressure. Without the jackets in use the amount of feed water per I.H.P. per hour was 17.22 lbs., and with the jackets in use 15.45 lbs., showing a percentage of less steam used owing to the jacket of 10.3. The total jacket water was 1.72 lbs. per I.H.P. per hour. The coal consumption is given in these experiments, being 2.09 lbs. per I.H.P. per hour without the jackets, and 1.79 lbs. with. The amount of coal burnt is not, of course, necessarily a measure of economy of the engine, but possibly the steam-generating plant—which included an economizer—was practically constant in its duty during both trials, and if so the commercial gain by the use of the jacket is quite an appreciable quantity. The boiler pressure here was 130 lbs. above atmosphere, the number of expansions without the jacket 22, and with the jacket 30. The revolutions were 23 per minute, so that the jacket had again a favourable chance.

The next series of experiments were carried out by Colonel English, Mr. Davey, and Mr. Bryan Donkin, and in these we reach a much higher piston speed, so that the results stand on a somewhat different footing in this respect to those before quoted. We have no positive knowledge of this engine beyond that given in the report, but it would be desirable to know something more of its working before accepting the very high percentage of gain in steam used—19.0 per cent—as that due to a steam jacket used on a good engine. The feed used per I.H.P. per hour was 24.68 lbs. without the jacket, and with the jacket in use the quantity was 20 lbs. The following are the particulars of this trial.—Horizontal surface condensing compound engine, with intermediate receiver cylinders, 18 and 32 ins. by 48 ins. stroke. The ends of the cylinders are not jacketed, and the receiver jacket was not in use during the experiment. The boiler pressure was 50 lbs., the revolutions 57.06 without jackets, and 63.62 with, the feed water supply as stated, and the jacket water condensed per I.H.P. per hour 1.13 lbs. The coal used without jackets was 3.26 lbs. per I.H.P. per hour, and with jackets 2.66 lbs.

The last set of experiments we shall quote were made by Prof. Unwin, upon the experimental engine<sup>1</sup> at the City and Guilds of London Central Institution, South Kensington. It is a two-cylinder horizontal surface condensing engine, and can be worked either simple or compound. The cylinders are 8.73 inch and 15.76 in diameter, by 22" stroke. The high pressure cylinder is fitted with Hartnell expansion gear, and the low pressure with Meyer expansion gear. Only the bodies and the back ends of the cylinders are covered. We will first give results of trials working the engine with the low pressure cylinder only. The pressure was 60 lbs. above atmosphere, the jacket pressure being taken direct from the boiler. The revolutions without the jacket were 112.40, and with the jacket 101.73. The feed water per I.H.P. per hour without the jacket was 32.14 lbs., and with the jacket 26.69 lbs. This gives a saving of 17 per cent working simple. It will be seen presently that when the engine was working compound, the saving was 7.3 per cent. The jacket-water per I.H.P. per hour was 1.88 lbs. We will now take the records of the compound trial. The boiler pressure was 66.73 lbs. without the cylinders, and 67.80 lbs. with the jackets. The revolutions were 93.66 without the jacket, and 96.11 with. The feed water used per I.H.P. per hour was 21.06 lbs. without the jackets in use, and 19.52 lbs. with. The saving, as stated, made by the use of the jacket

was therefore 7.3 per cent. The jacket water used per I.H.P. per hour was 2.40 lbs. We regret we are not able to give all the interesting details which Prof. Unwin includes in his instructive report, but for these we must refer our readers to the original paper.

Probably Prof. Unwin's 7.3 per cent saving in steam used is a far better measure of the value of the jacket than the inflated promise of 19 per cent in Major English's trial. It should be remembered that the jacket is more effective in small than in large engines, the area of cylinder will be in a higher ratio to the contained steam in the former than in the latter case. The number of expansions in the South Kensington engine working without jackets was 7.23, and with jackets 9.29. The corresponding figures in the case of the Woolwich engine were 9.4 and 12.6. The boiler pressure with the Woolwich engine was, however, 16 to 17 lbs. higher than in the other case. The revolutions were 57.06 and 63.62 respectively in the two trials at Woolwich, whilst at South Kensington they were 93.66 and 96.11. It would have been instructive if the committee had had the courage to attempt some balance of these figures, and then have endeavoured to account for the large difference which we believe would have remained still to be accounted for.

The next experiments quoted comprise a series made by Mr. Bryan Donkin, junr., at the works of his firm at Bermondsey. Mr. Donkin's labours in this field are well known, and engineering science is largely indebted to him for the contributions he has made to its lore. One most valuable feature in connection with these investigations is the means he has used to ascertain the temperature of the walls of the cylinder at various distances from the surface. In this lies the essence of the problem. If the jackets (committee would give us minute and trustworthy information on this point we could evolve the rest from existing data. If we do not quote Donkin's figures in full it is partly because his experiments are not yet complete and partly because they have been dealt with more fully in "another place," namely, the Proceedings of a Society other than that with which we are now dealing.<sup>1</sup> We may state, however, that in one case when the steam in the jacket space was 298° Fahr. the cylinder walls averaged 290° Fahr., whilst at 0.06 in from the piston the temperature of the cylinder wall was 284° Fahr. These temperatures were ascertained by thermometers placed in holes drilled in the cylinder. Other instances are given, but the matter is far too interesting to deal with in a cursory manner, such as a report of this nature alone warrants. The difficulty that suggests itself is the fact that a thermometer itself has a very appreciable thickness, and the record will be but a mean of the temperature due to that thickness. It is possible that Mr. Donkin gets over this difficulty in some way. Perhaps the thermo-couple as used by Le Chatelier might afford a solution, although this apparatus is not so useful for recording small differences at low temperatures, being rather adapted for such work as hot blast stoves and other metallurgical purposes. Mr. Bryan Donkin's experiments are the most suggestive in the report, as might be anticipated. Trials were made with steam at various rates of expansion to determine the effects of the steam jacket on the speed of engine and temperature of the cylinder walls, and on superheating. The engine used was a small one (6" x 8"), but it was specially constructed and arranged for the work. We again repeat Mr. Donkin's investigations are well worthy of the study of all interested in these matters.

The report concludes with a valuable appendix in the shape of suggestions for the use of those desirous of experimenting in this field.

The discussion on this paper was of a protracted nature, but was not of a kind altogether worthy of the leading mechanical institution of the country. Mr. Morrison, of Hartlepool, made the most weighty contribution amongst the speakers. He pointed out the difficulty of maintaining a good circulation of steam in the jacket—one of the most important points to which the designer of jacketed engines should turn his attention—and illustrated a simple method by which he had secured this end. His arrangement consisted of a series of diaphragms, by means of which the steam was made to take a devious course through the jacket. Mr. Schonheyder pointed out a mistake the committee had made in placing an air cock on the top of the jacket, when it was required to draw off air from the steam. Of course, this is one of those little slips which the wisest are apt to make, for it would be absurd to suppose such authorities as those en-

<sup>1</sup> See Proceedings Inst. Civil Engineers.

<sup>\*</sup> This engine is stated in the report to have been fully illustrated and described in *Engineering* of November 16, 1888. The triple expansion engine at Waltham Abbey is also said to have been illustrated and described in the issue of August 8, 1891, of the same publication.

gaged did not know that air is heavier than steam. One might as well say one's grocer did not know sand from sugar.

The Jackets Committee has not yet concluded its labours, and another report will be forthcoming in due course. Mr Aspinall has offered a locomotive for trial, and we heard that Mr Yarrow will put a torpedo boat at the disposal of the committee, and has even promised to cast special cylinders for experimental purposes. The locomotive will afford an interesting field of research, running as it does so largely linked up. The torpedo boat experiments will be no less interesting, especially in view of the great number of revolutions the engines of these craft make in a given time.

On the second day of the meeting the paper by Mr Walker of Bristol on the screw propeller. This paper gives the details of some experiments made by the author on a form of screw propeller invented by the late Mr B Dickinson. It would be in vain for us to attempt to condense this paper within the limits at our disposal. With regard to the merits of the Dickinson propeller we have nothing to say. It consists essentially of two narrow blades in place of one, and reminds us strongly of a Mangin propeller with one blade set somewhat back on the shaft. Mr Walker contends that his researches prove the advantages of long narrow blades, but he did not appear to have converted the high authorities present, including Mr Froude, Mr Thorneycroft, and Mr Barnaby—the three best-known names in connection with the subject—to his views. It is difficult to see wherein the value of the paper exists. Prof Kennedy in the discussion stated that the generally received opinion as to the increase of the friction of the load was erroneous, and that the power absorbed in this way does not increase in the manner stated, a fact which he illustrated by means of a diagram. Mr Thorneycroft pointed out that "life was not long enough" for the larger trials proposed by the author, but that he might decide one point if he would confine himself to models. Mr Barnaby stated that a broad bladed propeller should not be a uniform pitch. Mr Froude's speech was a lucid criticism of the author's paper, the speaker pointing out in a kindly but convincing manner that the conclusions arrived at by the author might be subject to revision. Mr Dunell, whose previous experiments the author had quoted, added to the information given by putting forward some other experiments he had made upon screw propellers fitted to a torpedo boat, in this case the results being opposed to those claimed by the author, inasmuch as the shorter and broader blade had proved the more advantageous. Mr Shield, of Liverpool, described a form of propeller which has been in use on the Mersey, and appears to offer some advantages. The blades are attached to the boss in two parts, and are joined in a loop at the top. According to Mr Shield's statement, the arrangement gives great advantages in towing, and also increased steadiness in running. The latter we can accept as a fact, but the great increase in towing capacity seems almost too good to be accepted literally. Twenty five per cent additional efficiency is a very large gain without further expenditure than an exchange of screws, but this is what the propeller in question is said to realize.

The meeting concluded with the usual votes of thanks.

### INTERNATIONAL COMMITTEE OF WEIGHTS AND MEASURES

THE International Committee of Weights and Measures, which was established in consequence of the Metric Convention of 1873, has recently issued its fifteenth annual report to the Governments represented at that Convention.<sup>1</sup> The committee have also lately published the minutes of their proceedings (*Procès-Verbaux des Séances*, Paris, 1892, 1 vol 8vo) at the annual meeting held at Paris in September, 1891. It appears to be hardly possible that the proceedings of the committee at their meeting which was held last month may be issued before next year, but from the above publications, as well as from a recent volume of their "*Travaux et Mémoires*," we gather that they continue to carry on their investigations with all despatch.

In their last report the committee deplore the death of their colleague, Jean Servais Stas, whose analyses of the platinum alloys have, together with those of St. Claire Deville and George

Matthey, so largely helped forward the principal work of the committee, the metallurgical studies of Stas are indeed recognized as veritable models of classical research in this particular field.

The new instruments added to the Bureau at Sèvres during the last year include a normal barometer (le Baromètre Fues) and manometer, originally verified for reference as an international standard in accordance with the decisions of the Meteorological Conferences, particularly that at Munich last year. The committee have also obtained a new apparatus for determining the normal thermometric "boiling point," or the temperature of 100° Centigrade, as it has been found that the form of apparatus used by Regnault was unreliable for this purpose. In the reading of the standard manometer it would appear that higher accuracy has been obtained by raising the surface of the mercury up to a fixed point, the image of the point in the mercury being observed at the same time by means of a microscope. The Wild-Pernet barometer has been remounted, and the Bureau are now prepared to undertake the verification of any standard barometer.

The readings of all mercurial thermometers are given at the Bureau in terms of the hydrogen thermometer, and a 30 litre holder for methyl chloride, or liquid carbonic acid, has been made by Brignonnet and Naville. The low temperature experiments have been continued by M. Chappuis down to -75° Cent., and toluol and alcohol thermometers have been compared with the hydrogen thermometer. It has been found that "toluol" is more sensitive and reliable for low temperatures than alcohol.

We note that the meteorological work of the committee has largely developed itself, and that, as in geodetic research, the Bureau at Sèvres is now recognized as a central and international station of reference. Standard thermometers have been verified, for instance during 1892, for the Governments of Russia, France, and Roumania, for the Universities of Rome, St. Petersburg, and Odessa, for Owens College, Manchester, and for several recognized meteorological observatories. Great Britain has also been supplied by the committee with standard thermometers similar to those supplied to other contracting States.

Besides the standard metre and kilogramme already delivered to this country, the Bureau is undertaking the construction of a further standard metre for the Board of Trade, at a cost of 12,588 francs. The new standard appears to have been nearly two years in construction, but its verification is now promised this year.

There are twenty one different governments who have joined the Convention and who contribute annually towards the expenses of the Bureau (the annual budget of which is 75,000 francs), sums varying from 134 francs (Denmark) to 9482 francs (Germany) the annual contribution of Great Britain and Ireland for 1892 being stated at 4699 francs, or nearly £188, and that of the United States at 8471 francs.

At the instance of Dr B. A. Gould the committee are now also undertaking an inquiry affecting measurement by light waves. By the use of the "Refractometer" Dr Michelson found (*Philosophical Magazine*, April, 1891, and September, 1892) that accuracy of measurement by light waves may be increased to a high degree of accuracy. By the best spectroscopic instruments now in use it has been stated to be difficult to "resolve" lines as close together as the components of the yellow sodium lines, but that if the width of the lines themselves be less than their distances apart, then there is no limit to their accuracy of measurement by the "Refractometer." We shall look forward with interest to the publication of Dr Michelson's further results, in the next volume of the "*Travaux et Mémoires*" of this committee.

The new instrument designed by M. Gustave Tresca, of the Conservatoire des Arts et Métiers at Paris, for the adjustment and polishing of the terminal surfaces of end measures of length appears also to be better than anything yet adopted in England.

The committee not only undertake the verification of standards and instruments for the High Contracting Governments (who have the right to demand such verifications), but they also verify for any scientific authorities or persons. To those of our readers, therefore, who may desire to have standards or instruments verified by the committee, the following information may be useful:—

Applications for the verification of instruments should first be made to M. le Directeur du Bureau International (Dr René-Benoît), au Pavillon de Breteuil, Sèvres, près de Paris.

<sup>1</sup> Rapport du Comité International. Gauthier-Villars. Paris. 1 Vol. 50 pp., 1892.

Standards may be sent to Sevres by post or railway (at the cost and risk of the owner), or still better, they may be delivered and removed from the Bureau by the owner or his agent. A certificate of verification will be given when the standards are ready for removal. In any application to the director the denomination of the standard, or the description of the instrument, should be stated, and the nature and extent of the verification demanded.

The committee will verify metric standards of length of one, two, three, and four metres, or subdivisions of the standard metre, if made in metal or some durable stone. Line measures should have their graduations so fine as to be well observed with a microscopic power of sixty diameters, and end measures should have their terminal surfaces sufficiently adjusted and polished so as accurately to define the length of the bar. Measures of mass may be made also of metal or some durable stone, but each must be in one piece without handles, grooves, or adjusting holes. For thermometers and barometers special regulations are issued, which may be obtained at a small charge from MM Gauthier Villars, 55, Quai des Grand Augustins, Paris.

The fees on verification of measures of length vary from 60 to 400 francs, according, of course, to the extent of the verification demanded, for metric weights from 20 to 120 francs, and for thermometers and barometers from 10 to 80 francs.

What should be the true equivalent length of the yard measure in terms of the metre, may appear to some to be almost a trifling matter—because the measurement in dispute, or probable error of the equivalent at present adopted in this country, amounts only to 0.0008 inch. It is, however, a fact that so small a difference as 0.0008 in this equivalent would not only be felt in scientific researches but also in practical work. Messrs Comstock and Tiltman, of the United Coast Survey, as well as Dr Peters, of Germany, and the Director of the International Committee, have found that the equivalent length of the metre (39.3708 inches) as ascertained by Kater and Arago, in 1818, is inaccurate, to the extent of 0.0008 inch, and that the true equivalent ought to be nearly 39.3700 inches. This latter value will, we have no doubt, be ultimately recognized in scientific work.

In the field of electrical measurements, we find that Dr Guillaume is continuing his investigations as to the measurement of temperature by electrical methods, and as to the variations of mercurial standards of resistance, a work originally begun at the Bureau, by Dr Benoit, in connection with the standard ohm. It would not appear that mercurial thermometers can be superseded for ordinary measurements of temperature, but that measurement by resistances may afford useful results in determining the temperature of a given mass or space, as the whole length of a column of mercury. Dr Guillaume gives an account of his work on mercurial standards in the *Process-Verbaux* recently issued (page 183).

During the past year Commandant Defforges, of the Geographical service of the French army, has been undertaking at the Bureau an inquiry into the effect of the force of gravity at the latitude of Breteuil, by means of a seconds pendulum and apparatus constructed by Brunner. M. Defforges found that at Breteuil (longitude east of Paris  $0^{\circ} 13'$ , latitude north  $54^{\circ} 26'$ , and altitude 70.4 metres)  $G = 9.80991$  m.

We cannot conclude this glance at the recent work of the International Committee without expressing an opinion that the scientific success of their work and the accuracy of its record, owe much to the energy and watchful care of its new president, Dr Foerster, and the secretary of the committee, Dr. A. Hirsch.

#### NOTES ON SOME ANCIENT DYES<sup>1</sup>

THE fragments of ancient dyed fabrics which I have examined I owe to the kindness of Mr R D Darbishire. They are specimens from a lot found by Mr. Flinders Petrie in a tomb at Garob, Lower Egypt, supposed to date from 400–500 A.D. They were used apparently for filling the mummy cases where required, not strictly speaking as grave clothes. My object in examining them was to ascertain, if possible, what were the materials employed in producing the various colours seen on

them. The fabrics examined consisted almost entirely of wool. Here and there in the warp of some of the specimens were threads, conspicuous for difference in colour, consisting of linen. The following colours could be distinguished:—blue, yellow, green, red, maroon, purple or claret, black. I will take them in the order named.

*Blue*—The colour of the fabric was a dull medium blue. On treatment with hot caustic lye a great part of the wool dissolved. The residue, which was dark blue, having been filtered off, washed and dried, was treated with boiling aniline, to which it communicated a bright blue colour. The blue solution having been filtered boiling, deposited on cooling a quantity of blue crystalline scales, which, after being filtered off, washed with alcohol and dried, were found to consist of indigo blue. On being treated in a tube they gave a sublimate of regular crystals, blue by transmitted, copper-coloured by reflected, light, they dissolved in concentrated sulphuric acid, giving a blue solution, and the solution in aniline showed the absorption spectrum of indigo blue. It is evident, therefore, that indigo in some form or other was the material used in dyeing this colour.

*Yellow*—The colour of the patches dyed yellow was so evidently faded, and showed so little intensity, as to make it very uncertain whether analysis would lead to any precise result, the examination was therefore omitted.

*Green*—Of the material dyed this colour, I had but a small quantity, but it was sufficient to allow of some conclusion regarding the means whereby the colour was produced. On being treated for some days with dilute hydrochloric acid it imparted to the latter a deep yellow colour. The portion left by the acid, after being washed and dried, yielded indigo blue on treatment with boiling aniline. It is probable, therefore, that the colour was produced by first dyeing the fabric with indigo, then treating with some mordant, such as alum, and, lastly, dyeing with some yellow colouring matter, most likely of vegetable origin. With the small quantity of material at my disposal, I found it impossible to ascertain the nature of the yellow colouring matter employed.

*Red*—This was the most pronounced, and at the same time the most interesting, of the colours examined. The colour of the fabric was a full deep red. It might be called a Turkey red, the dye, in fact, proved on examination to be a kind of Turkey red as having the characteristic properties of that dye.

On being burnt, the fabric left a considerable quantity of ash, consisting of calcium sulphate, alumina, aluminium phosphate, ferric oxide, and silica. A large portion of this ash no doubt represents the mordant employed in producing the colour. On treatment with hot dilute hydrochloric acid, the fabric lost its red colour and became yellow. After removal of the acid by washing with water, and pressing between blotting paper, treatment with boiling alcohol deprived the wool of the greater part of the yellow colour, a faint tinge only being left. The deep yellow alcoholic liquid obtained left on evaporation a reddish-brown amorphous residue. This, on being treated with a boiling solution of alum, dissolved in part, yielding a pink fluorescent liquid, which had exactly the same colour, and showed precisely the same absorption bands as a solution of purpurin from madder in alum liquor. On adding hydrochloric acid to the pink solution and heating, the colouring matter was precipitated in orange-coloured flocks, the liquid becoming almost colourless. The flocks after being filtered off and washed with water dissolved easily in boiling alcohol, yielding a yellow solution, which, on spontaneous evaporation, left a quantity of dark yellow needles arranged in rosettes. These needles dissolved in caustic alkali, giving a cherry red solution, which showed the absorption bands of purpurin. The solution, on exposure to air and light, became colourless.

Some of the precipitated colouring matter, on being employed in the usual way for dyeing a bit of calico to which various mordants had been applied, yielded colours exactly like those obtained with purpurin from madder, i.e., the alumina mordant gave a bright red, the iron mordant dull purple to black tints. The matter left undissolved, after repeated treatment with boiling alum liquor, was still highly coloured. It dissolved easily in alcohol, the solution leaving on evaporation a brown amorphous residue, which remained soft even after long standing. This residue consisted for the most part of fatty matter, but it also contained some colouring matter insoluble in alum liquor. That this colouring matter was alizarin seemed probable, since the colour which the mixture imparted to alka-

<sup>1</sup> Reprinted from "Memoirs and Proceedings of the Manchester Literary and Philosophical Society," 1891-92 (Fourth Series, vol. 5, No. 2).

line lye resembled that of an alkaline solution of impure alizarin.

These experiments lead to the conclusion that the red colour of the fabric was produced by dyeing with some kind of madder, either wild or cultivated, the fabric having been previously treated with a mixed aluminous and ferric mordant, and then probably oiled—that it was, in fact really a kind of Turkey red.

**Maroon**—The dull chestnut colour of this fabric presented a striking contrast to the bright red of the preceding. Its constitution was, however, similar. Having treated it in the same way as the other, I found that the colouring matter must have been derived from madder, fatty matter was also present, but the mordant contained a larger proportion of ferric oxide, a fact which sufficiently explains the brown tint of the dyed fabric.

**Purple**—The fabric in which this colour was seen was made up of a pale yellow warp, and a weft of a dull purple or claret colour. The latter colour was found to be due to an intimate mixture of red and blue, for the threads, on examination under the microscope, were seen to consist partly of red, partly of blue fibres, the former predominating. The two sets of fibres had, of course, been mixed before spinning. The blue fibres were certainly dyed with indigo, the red probably with madder.

**Black**—The colour of the black fabric, like that of the green, was a compound of two colours, one overlying the other. Under the microscope the individual threads appeared grey. On treatment with a mixture of alcohol and hydrochloric acid they changed colour, a yellow liquid being obtained, while the fabric itself now appeared blue, and after washing and drying yielded indigo by appropriate treatment. The yellow alcoholic liquid was found to contain purpurin. The colour may be supposed to have been produced in the following manner—The woollen fabric having first been dyed blue was morlanded, to use a modern phrase, and then dyed with madder, the two colours together producing the effect of black.

EDWARD SCHÜNCK

### SCIENTIFIC SERIALS

In the *Botanical Gazette* for July, August, and September, there are several papers of general interest. Mr G. A. Rex presents a further contribution to our knowledge of the Myxomycetes in an account of the genus *Linbladia*.—Mr D. F. McDougal gives a detailed account of the morphology and anatomy of the tendrils of *Passiflora carulea*.—Mr M. B. Thomas describes and figures an apparatus for determining the periodicity of root pressure in plants.—Mr C. L. Holtzman has a short paper on the Apical growth of the stem and the development of the sporangium in *Botrychium virginianum*, his observations favouring the view that the Ophioglossaceæ are a more primitive form than the typical Filices.—Mr A. F. Foerste continues his observations on the Relation of autumn to spring blossoming plants.—Mr Charles Robertson gives a further instalment of his series of papers on Flowers and insects.—A brief report is given of the botanical papers read at the recent meeting of the American Association for the Advancement of Science.

In the *Journal of Botany* for September and October, no less than four new species are added to the British flora and to science—*Hieracium hibernicum*, *H. duriceps*, and *H. Bical albanense*, by Mr F. J. Hanbury, and *Ranunculus petiolaris* (sect. *Flammula*) by Rev E. S. Marshall.—Rev W. Moyle Rogers continues his Essay at a key to British Rubi, Mr E. G. Baker his Synopsis of genera and species of Malvæ, and Mr W. A. Clarke his First Records of British Flowering Plants.

*Bulletin of the New York Mathematical Society*. Vol. II. No. 1, October, 1892. (New York).—Prof Cajori opens this number with an interesting note on the evolution of criteria of convergence (pp. 1-10), in which he discusses some special and general criteria furnished in the writings of Gauss, Cauchy, Abel, DeMorgan, Bertrand, Kummer, and others, and notices specially the remarkable advance made by Pringsheim (*Math. Ann.* vol. xxxv.).—Dr A. Martin calls attention (pp. 10-11) to a slip in Ball's "Short History of Mathematics" (p. 102), the probable origin of which is accounted for by Mr Ball.—There

is a slight review of Chapman's "Elementary Course in the Theory of Equations" (pp. 11-12), and the rest of the issue is taken up with the usual list of new publications and notes. In these last Dr Martin points out a curious error in the Royal Society "Catalogue of Scientific Papers," vol. ix (1874-1883), where, of the papers accredited, on p. 790, to Ezekiel Brown Elliott, Nos. 5, 11, 14-17 should be assigned to Mr Edwin Bailey Elliott, of Oxford, and not to the late Mr Ezekiel Brown Elliott, of America, to whom Nos. 4, 12, 13 are rightly attributed.

In the *Bullettino* of the Botanical Society of Italy, we find in addition to papers of more local interest, a further communication from Sig. Macchiati on the Cultivation of diatoms, in which he states that the presence of infusoria and of diatoms in the water is mutually beneficial to one another, while the most destructive enemies of the latter are bacteria.—A paper by Sig. Piccioli on the Biological relations between plants and snails, is chiefly devoted to the protective contrivances found in the former against the attacks of the latter, the most important of which are of a chemical nature—tannin, latex, oleiferous glands, and poisonous salts such as calcium oxalate—mechanical means of protection, such as hairs and a comparatively thick cuticle, play a subordinate part.—In a further communication by Prof. Arcangeli on the Cultivation of *Cynomorium coccineum* he states that he does not find such an intimate parasitism with its host as is the case with the Rafflesiaceæ and the Balanophoraceæ.

### SOCIETIES AND ACADEMIES

#### PARIS

Academy of Sciences, October 24.—M. de Lacaze Duthiers in the chair.—Researches on the fixation of atmospheric nitrogen by microbes, by M. Berthelot. The investigation was made in order to elucidate the mechanism of the fixation of atmospheric nitrogen. It appears that the presence of green vegetable material is not essential to the process. The colourless bacteria are able to absorb nitrogen when supplied with humic acid only as nutriment. The assimilation takes place more readily with natural than with artificial humic acid, probably because the former contains more nitrogen. In experiments with hermetically sealed cultivations it was found that the gain of nitrogen by the organic material under cultivation was 6 or 9 per cent in excess of that supplied by the humic acid, the difference being derived from the enclosed air. With an occasional stream of dust laden air this was brought up to 30 per cent.—Coloured photographs of the spectrum of albumen and bichromated gelatine, by M. G. Lippmann. Albumenized and gelatinized plates soaked in bichromate of potash may be employed for photographing in colours. They are used like silver salt plates, being placed so that the mercury is in contact with the film. The colours will appear immediately after immersion in water, which develops and also fixes the image. It disappears on drying, but reappears as soon as the plate is soaked. The colours are very brilliant, and visible at all angles. Those of gelatine plates are brought out by simple breathing. The theory is analogous to that of silver plates, the maxima and minima of interference producing hygroscopic and non hygroscopic layers with varying refractive indices.—The irrigation canals of the Rhone, by M. Chamberlont.—A new apparatus, the schisophon, serving the purpose of exploring the internal structure of metallic masses by means of an electro-mechanical process, by M. de Place. The apparatus consists of a microphone and an induction sonometer. To the microphone is attached a rod of hard steel, kept oscillating once or twice per second, and striking each time against the casting or other mass of metal under investigation. The sonometer, consisting of two coils movable towards or away from each other along a divided scale, with a telephone connected with one of the coils, is placed in another room, and joined by wires to the microphone. The coils being so adjusted that the tapping is scarcely perceptible at the sonometer, the casting is moved so as to expose various portions to the impacts. If the thickness be uniform, any flaw or fissure will be at once indicated by a change in the sound.—Observations of the comet Barnard (D 1892), made at the Paris Observatory, by M. G. Bigourdan.

—Elements of the comet Barnard, of October 12, 1892, by M. L. Schulhof —On the algebraic integrals of the differential equation of the first order, by M. L. Autonne —On centres of geodesic curvature, by M. Th. Caronnet —On Pfaff's problem, by M. A. J. Stodolkevita —Sunspots and magnetic disturbances in 1892, by M. Riccio —On considerations of homogeneity in physics, reply to M. Clavenad, by M. Vaschy —Verification of parallelism of optic axes in uniaxial crystalline plates, by M. Bernard Brunhes —On a photometric photometer, for the measurement of feeble illuminations, by M. Charles Henry —This is based upon the constancy of the phosphorescent sulphide of zinc. Its law of loss of brilliance being determined, it may be used for measuring very feeble illuminations, such as distant artificial light or the general luminosity of the sky due to the stars. The decrease of light after the first 900 seconds being given by  $t^{0.1} (t - 185) = \text{const}$ , it is easy to calculate the luminosity at any instant. In the instrument in question there are two screens of ground glass, one of which is illuminated by the phosphorescent sulphide, brought to its maximum glow at a certain time by burning magnesium ribbon, the other exposed to the source of light. It is then only necessary to wait till both the screens are equally illuminated, and to note the time —On the dissociation of chrome alum, by MM. H. Bauoigny and E. Pechard —On the temperatures of maximum density of aqueous solutions, by M. L. de Coppet —On some double salts of quinine, by M. E. Grimaux —On the thermal value of the three functions of orthophosphoric acid, and on its constitution, by M. de Forcrand —Preparation and properties of fibroine, by M. Leo Vignon —Regeneration of the so-called sporozoa form in the diatoms, by M. P. Miquel —On the hematozoaria of cold-blooded vertebrates, by M. Alphonse Labbe —Influence of coloured light on the development of animals, by M. E. Yung —On the mode of fixation of the hexapod parasitic larvae of the acarians, by M. S. Jourdain —The cavern of Brassempouy, by M. Edouard Piette —Discovery of a skeleton of *Elephas meridionalis* in the basaltic ashes of the volcano of Senez, by M. Marcellin Boule —Vegetable prints of the Dover boring, by M. R. Zeiller

## BERLIN

Meteorological Society, October 11 —Prof. von Bezold, president, in the chair —Dr. Berson reported on an interesting relationship which he had discovered between insolation and temperature. Since it has not yet been possible to determine accurately the absorption due to the atmosphere, the speaker had calculated the insolation at the external limit of the atmosphere, which admits of rigid mathematical treatment, both for the whole year and for the months of January and July. The mean of insolation for the whole year was found to lie at the thirtieth degrees of northerly and southerly latitude, so that the zone between these parallels, or about 60 per cent of the whole external surface, receives more insolation than the mean, whereas the two polar caps, or the remaining 40 per cent, receive less. A similar calculation of the annual temperature gave the mean as at latitude  $38^{\circ}$  N and  $35^{\circ}$  S, giving as before 60 per cent of the surface with the temperature above the mean, and 40 per cent below. In January 61.35 per cent of the surface experienced an insolation above the mean and 60 per cent a temperature above the mean, while in July the percentages were respectively 61.37 and 61.33. —Dr. Zenker gave a short account of a research on the relationship between temperature and insolation on the earth's surface. He had accurately calculated the relationship both for regions comprising land only and water only, and arrived at some interesting conclusions as to the theoretical temperatures at various latitudes of continents and oceans.

Physical Society, October 21 —Prof. Kundt, president, in the chair —Dr. Jager gave an account of the measurements he had made, in conjunction with Dr. Kreischaugauer, of the temperature-coefficient of electric conductivity of mercury. Dr. Arons demonstrated an arc light between mercurial electrodes in vacuo. It yielded a dazzling white light, which was steady at the anode but flickered and jumped at the cathode. Its intensity approximated to that of an ordinary carbon arc-light. The heat given off by it was but slight so that the tube could be held in the hand; the temperature was highest at the cathode. Attempts were made to determine the resistance of the arc, but without result. It was found by the use of a telephone that the current is discontinuous. A spectroscopic investigation of the light revealed a lime-spectrum showing very

brilliantly a yellow, a green, and a blue line. In addition to the ordinary lines due to mercury some twenty new lines were observed. No satisfactory results were obtained by using amalgams instead of mercury, with the one exception of sodium amalgam. It is proposed to make further experiments with fluid amalgams of sodium and potassium.

## EXPERIMENTAL BIOLOGY

*Experimental Evolution* By Henry de Varigny, D Sc.  
(London Macmillan, 1892)

DR HENRY DE VARIGNY has enriched the literature of biology by publishing in the "Nature Series" the lectures on "Experimental Evolution" delivered by him in 1891 to the Summer School of Art and Science in Edinburgh. This school, as is well known, has been doing good work on Extension lines in Edinburgh, and Prof Geddes is to be congratulated on having secured the co-operation of so able a biologist and so ardent an exponent of the special aspects of biology with which he has identified himself as M de Varigny. The lectures are well worthy of publication, for they contain a rich, well-ordered, and, for the most part, well sifted body of facts collected from many sources, and especially from the publications of French naturalists. But the author is more than a collector of facts recorded by other workers, he is himself a worker in this special field of biological science. And some of the most valuable of his observations contained in the work are the result of his own careful and exact investigations.

Experimental biology is still in its infancy. It is true that our domesticated animals and plants are the result of much experimental work in the past, but the experiments were not planned with the object of explaining organic nature, and were therefore not biological in their aim. There is pressing need at the present time for experiments with such definite scientific aim, for experiments, that is to say, carried out with the express object of testing the truth of biological principles. And that this work be well done there is pressing need for organization. We have only to look at the results which have been reached by well-planned and well-directed marine stations in extending our biological knowledge, faunal, morphological, and embryological, to see what may be done by organization of research. What Dr de Varigny eloquently pleads for, and what our own countryman, Dr Romanes, is also pleading for, is an experimental institute, well planned and adequately supported, the purpose of which shall be to carry out extensive experiments for testing evolution hypotheses in all their bearings.

"It appears to me," says Dr. de Varigny, "that this institution should comprise the following essential elements:—Rather extensive grounds, a farm with men experienced in breeding, agriculture, and horticulture, some greenhouses, and a laboratory with the common appliances of chemistry, physiology, and histology. Of course this must be located in the country. It is very important to have experienced farm hands, and a good chemist and histologist are necessary in the staff of the institution. As to the general management, it seems advisable to have a director with a board of competent men, whose functions would be to decide, after careful investigation and exchange of views, what are the fundamental experiments to be performed. These experiments, when once decided upon, should be pursued

during a long period of years, and nothing should be altered in their execution unless considered advisable by the board, or unless the experiment should be found useless, or devoid of chance of success. The main thing should be to provide for the duration of the experiment, whether the originators were living or dead, and to follow it out for a long time. Time is an indispensable element in such investigations, and experiments of this sort will surely exceed the normal duration of human lifetime."

A special branch of the work of such an institute should be experimental investigations in comparative psychology. Of this there is nowadays some need. Speaking of the transmission of acquired characters, Dr de Varigny says, "Psychology affords similar instances. A kitten which has never seen a dog is afraid from the first moment it perceives one, young birds of many species instinctively fear the hawk and other birds of prey, while remaining unaffected by the presence of other birds. Are not these psychological 'attitudes' due to environment (acting on the *mens* of ancestors) which have been transmitted by inheritance, are these not *acquired characters*?" From observations of my own I am prepared to say that it is by no means universally true that a kitten which has never seen a dog is afraid from the first moment it perceives one. Mr Spalding does indeed describe how the smell of his hand with which he had been fondling a dog set four blind kittens puffing and spitting in a most comical fashion. But a careful observer, Mr Mann Jones, writes to me that a young kitten with which he experimented "took eight days to connect the smell or odour of his hand with the thing—dog." And my own observations are confirmatory of those of Mr Mann Jones. Mr Hudson, in a very interesting chapter of the "Naturalist in La Plata," gives observations which tend to show that young birds afford little evidence of instinctive fear of particular enemies, and my own experiments with young chicks lead me to believe that they have no instinctive knowledge of the things of this world. Any unusual and sharp sound (*e.g.*, a chord on the violin), any large approaching object (*e.g.*, a ball rolled towards them), causes alarm. There is no evidence of instinctive particularization of alarming objects. Such observations lead me to look with suspicion on any arguments for the transmission of acquired characters based on supposed instinctive knowledge of things. And they show the need of further research in comparative psychology such as could be carried out at the Institute of Experimental Biology.

It may be said that the central hypothesis of modern evolution, that of natural selection, stands in no need of experimental verification. But it will presumably be admitted, even by those who are firm in their belief, among whom I count myself, that further experimental support will be of the utmost value. There are many who assume a sceptical attitude, and who say—We grant the inexorable logic of your conclusions if your premisses be established. More individuals are born than can or do survive, the devil devours the hindmost, and a beneficent selection rewards the survivors with the privilege of procreation. Hence, progress towards increased adaptation. A very pretty piece of logic. But now, they say, show us the devil at work. We pretend to no particular knowledge

of these matters, but we are quite ready to be convinced by proven facts. Prove to us this devil's work, and we acquiesce in your conclusion. But do not put us off with a logical "must be," the recognized symbol of an assumption. Do not tell us that since a hundred were born and only two survive, the ninety-eight must be in some way and for some reason unfit. This is just the very fact of which we require definite and indubitable evidence.

Now what solid and unimpeachable body of evidence have we wherewith to conclusively refute this scepticism? If animals or plants removed to a new environment assume a new habit, in how many cases is it clearly *proved* that this is due to the elimination of all those who failed to vary in the direction of this habit? It behoves us to be careful that the very strength of the natural selection hypothesis be not a source of weakness, by leading us to neglect the duty of experimental verification. That there should be a central institute or institutes for the purpose of such experimental verification, is what Dr de Varigny and Dr Romanes are pleading for. It would produce a salutary organization of research, for the institute would have carefully selected correspondents in all parts of the world who would carry out their experiments in concert. It would bring scattered energies to a focus. It would by its journal show individual workers where research is specially needed. It is bound to come sooner or later. We hope to see it an established fact before the close of the present century.

#### BRITISH FUNGUS FLORA

*British Fungus-Flora, a Classified Text-Book of Mycology*  
By George Massee. In 3 vols. Vol. I (London and New York: George Bell and Sons, 1892.)

IT was in 1836 that Berkeley published his "British Fungi" as a part of Hooker's "British Flora," and for about a quarter of a century this was the standard work. In 1860 appeared Berkeley's "Outlines of British Fungology," which from the first was disappointing, inasmuch as it was only a barren catalogue for all except the large and conspicuous species, and even the latter were so compressed in description, by the exigencies of confining the book within narrow and definite limits, that it did not wholly supersede the use of the old "British Fungi." In 1871 an effort was made to repair the error by the publication of Cooke's "Handbook of British Fungi," which brought the whole subject up to date, and gave a new impetus to British mycology. On account of the considerable acquisition of species, new to the British flora, it was deemed fitting in 1871 to produce a new work which should include these additions, and then Stevenson's "British Fungi" appeared. This new work only included the "Hymenomycetes," or, in effect, part of the first volume of Cooke's "Handbook," leaving all the rest untouched. In order to remedy this deficiency in part, Cooke's "Myxomycetes" was issued in 1877, and Phillips' "Manual of British Discomycetes" in 1887. Meanwhile a second edition of a portion of Cooke's "Handbook" was being issued as a supplement to "Grevillea," but confined exclusively to the *Agaricini*. With the exception of Plowright's "British Uredineæ" published in 1889, all the rest of the orders contained in

the "Handbook" remained as they were in 1871. The unrevised portions included the *Pyrenomycetes*, or Sphæriaceous fungi, the *Sphaeropsidæ*, or imperfect *Pyrenomycetes*, and the *Hyphomycetes*, or moulds. Hence the announcement of a complete work which should include *all* the British fungi, of whatever denomination, brought up to date, did not come as a surprise.

The volume before us consists of 430 pages, and professes to be the first of three volumes, which are to contain the whole "British Fungus Flora" in full, and upon the same plan as this first volume. We have heard of wonderful feats of "strong men," but these will be nothing in comparison to the feat which is ostensibly promised on the title-page, *when* it is accomplished. In our simplicity we should have calculated *six* volumes as nearer the minimum. If the result proves to be *less*, we shall be content to bear the odium of a false prophet. We may premise that the author who has undertaken the present work is eminently fitted to carry it out successfully, inasmuch as he is a practical field naturalist, with independent views, and by no means afraid of hard work.

To return to the volume in question, we must recognize clearness of typography, and distinctness in the isolation of species, which will facilitate reference and increase its practical utility. The illustrations are rather rough outlines, but quite sufficient for practical purposes, and will exhibit the distinctions between the several genera as far as illustrations can do it. Of the systematic arrangement we are not prepared to speak so highly, but perhaps some may consider this a matter of detail. The contents may be summarized thus, in the order of their appearance. The *Gastromycetes*, or puff-ball fungi, commencing with the subterranean species, followed by the *Sclerodermeæ* and the *Nidulariæ*, then the *Lycoperdæ*, concluding with the *Phalloidæ*. These are succeeded by the *Hymenomycetes*, in like manner inverted, commencing with the *Tremellinæ*, and backwards through the other families to the *Agaricini*, which are commenced in the last 120 pages, but not half completed. We imagine that half another volume will be required to complete the *Basidiomycetes*.

Under ordinary circumstances, when we take up a flora, we are accustomed to meet with the adoption of either one of two methods. The one consists of a regular sequence, from what the author regards as the highest developments in his congeries to the lowest, the other an equally regular sequence from the lowest to the highest. This is conventional, but the present book is not conventional. In one sense there undoubtedly is a regular sequence from the lowest forms to the highest in the *Basidiomycetes*, which this volume contains; but we must not infer that Mr. Massee regards the *Basidiomycetes* as the lowest order of Fungi, or that he commences with the simplest organisms, proceeding upwards by regular gradations to the most complex, when he starts with the *Gastromycetes*. Undoubtedly our author has not made a special study of the puff balls in order to degrade them to the lowest rank. Hence we can only arrive at one conclusion, and that is, that such portions of the work have now been printed as were ready for the press, and no conclusions are to be drawn from the sequence adopted as a convenience, as if it were adopted by premeditation.

Continental mycologists have now for some time accepted the genera of the *Agaricini* as defined by Fries, with the exception of the large genus *Agaricus*, which Fries himself subdivided into numerous smaller groups as subgenera, but they have elevated all these smaller groups to the rank of genera, and placed them upon an equality with the other veritable genera of *Agaricini*. Against this metamorphosis we feel bound to contend, on the ground that the distinctions, although sufficient for the subdivision of a genus, are not of generic value, and that the genera so constituted are unnecessary, and of unequal value, with the old genera beside which they are placed. For instance, *Amanitopsis* differs only from *Amanita* in the absence of a ring, and *Annellaria* differs only from *Panaeolus* in the presence of a ring. Let any one of practice and experience compare these pseudo-genera with *Coprinus*, *Cantharellus*, or *Schizophyllum*, and judge of what we say. For the first time these pseudo-genera now find a place in a British flora, and, although not of overwhelming importance, we cannot permit them to pass without protest.

Spore measurements are a recent addition to the diagnoses of *Hymenomycetes*, and, although we contend that they should be employed with caution and discrimination, it is very satisfactory that so much attention should have been given to them in this work. Not only does the spore vary in size in a given species in different seasons, but at different periods in the same year. This is certainly true in some species which have been tested, and should lead us to accept spore measurements as approximate rather than absolute.

In conclusion, we are bound to remark that this is a student's book, written with a full appreciation of the wants of a student, and giving all the information which a student might require. In all cases, whether under families, genera, or species, will be found just the details which the novice will be most anxious to obtain, and, although the study of these interesting but rather difficult plants has been of late somewhat upon the decline, we doubt not that it will revive and prosper by the aid of the new "British Fungus Flora," which will become the "text-book of British mycology." M. C. C.

### SOUTH AFRICAN SHELLS

*Marine Shells of South Africa*. A Catalogue of all the Known Species, with References to Figures in Various Works, Descriptions of New Species, and Figures of such as are new, little known, or hitherto unfigured. By G. B. Sowerby, F.L.S., F.Z.S. Pp. 89, 5 pls. [drawn by the author] (London, 1892).

SINCE 1848, when Krauss published his well-known work, entitled "Die Südafrikanischen Mollusken," no such list as the one before us dealing with the Molluscan Fauna of this interesting and important marine province has appeared.

Krauss, who included the non-marine forms of the South African region in his work, recorded 403 marine species, of which 213 were considered to be peculiar to the province. Many other species have been subsequently cited or described as coming from that quarter, notably by E. von Martens and by our present author.

Conchologists undoubtedly owe much to Mr. Sowerby

for thus bringing together within the small compass of this single volume, the scope and aim of which are sufficiently indicated in its title, the scattered records of the various species as known to him, but they will equally regret that the author did not include the whole molluscan fauna instead of confining himself to the testaceous forms, and thereby raise the work from the level of a mere shell-collector's catalogue to the rank of a work of reference of real scientific value.

Mr. Sowerby enumerates 740 species, and estimates that 323 of these are confined to South Africa, whilst 67 also occur in European seas, and 340 have been found on other coasts. Unfortunately, it is our disagreeable duty to point out that this record does not include "all the known species," and hence is not what the author fully intended it to be, viz., "as complete as possible." An important paper by Von Martens<sup>1</sup> appears to have been overlooked, for there are about thirty species named in it, including some which were then new, not mentioned by Mr. Sowerby. Still more remarkable is the omission of the new forms described by Mr. Watson in his report upon the Scaphopoda and Gastropoda, obtained during the voyage of the *Challenger*. Davidson's "Monograph of recent Brachiopoda," had it been more closely scanned, would have yielded not only two species reputed to have come from the Cape, but also *Terebratulina Davidsons*, King, the type specimens of which, dredged on the Agulhas Bank, were passed on to their describer by Mr. G. B. Sowerby (the elder, we presume) in 1871.

A number of species have been recorded by Mr. E. A. Smith in an appendix to a "Report on the Marine Molluscan Fauna of the Island of St. Helena,"<sup>2</sup> as found there on what is locally known as "Sea-horn." This substance appears to consist of portions of a large species of Tangle, probably *Echlonia buccinalis*, which occurs at the Cape, whence it drifts to St. Helena. Some allusion should have been made to these forms. Hints might also have been gleaned from the same report, which deserves to be more widely known than seemingly it is, of undoubted South African species whose names do not appear in Mr. Sowerby's catalogue.

The presence of a good index, while it obviates the necessity, does not abolish the desirability of a good classification, and, in the present state of our knowledge in matters conchological, that of Woodward's Manual is hardly up to date, it is somewhat late in the day to find *Dentalium* still in its old place in the Gastropoda.

Some few changes in nomenclature are made in deference to the law of priority, and these are set forth at the end of the preface. Amongst them is *Ovula*, Bruguière, 1789 = *Ovulum*, Sowerby, &c., though, according to some, *Ovula* is itself a synonym for *Amphiperas*, Gronovius, 1781. *Calliostoma* is erroneously attributed to Bruguière instead of Swainson.

There are also some oversights in the text, as, for instance, "*Columbella cerealis*, Menke (Buccinum), Krauss = *C. Kraussi*, Sowerby," where, since Menke's name was given merely in MS., Sowerby's name stands, having four years' priority over Krauss's. *Trisforis* is treated as though of the masculine gender, whilst the references to "figures in various works" require careful checking.

<sup>1</sup> "Ueber einige südafrikanische Mollusken nach der Sammlung von Dr. G. Fritsch." *Jahrb. Deutsch. Malak. Gesell.* 1874, pp. 119-146.

<sup>2</sup> *Proc. Zool. Soc.* 1890, pp. 347-377.

As regards the figures that accompany the work itself, it is a matter for regret that they cannot be commended. Few objects are more difficult to draw or require more skill in their delineation than do the shells of mollusca, and the amateur is rarely able to do them justice. The want of finish in the present instance is all the more noticeable from the contrast they afford to the rest of the "get up" of the work, which is admirable.

These shortcomings are not thus dwelt on in any captious spirit, but are pointed out in the friendly hope that a future edition of the work may shortly be forthcoming, in which the defects of the present one, compiled under great difficulties and at much disadvantage, may be made good and a really complete catalogue result.

(BV)<sup>2</sup>.

### OUR BOOK SHELF

*The Framework of Chemistry* Part I. By W. M. Williams, M.A. (London: George Bell and Sons, 1892.)

THIS is the first part of a book which has been specially written as a supplement to the oral lessons and experimental demonstrations given by a teacher. It is intended to contain nothing but what is absolutely necessary to give definite and precise impressions regarding the salient points of the lessons, all details relating to laboratory manipulation being omitted. The more important introductory facts, divested of theoretical considerations, are first discussed, then come "atoms and molecules," treated in an elementary fashion and leading the way to the explanation of the use of symbols and formulæ.

How the system adopted by the author will work out can only be ascertained when the other parts are to hand. So far as the information in the present volume goes, it is to a great extent useful and clearly stated.

Objection may be taken to the classification of solutions as mechanical and chemical, for, were it for no other reason, it is still a disputed point whether any solution may be considered a mixture.

The concise style of the book lends itself to incomplete statements. For instance, to say that one of the oxides of carbon "contains exactly twice as much oxygen as the other," is hardly accurate, a constant quantity of carbon is essential to the accurate conception of the facts. The most serious blunder made by the author lies in the confusion of force and energy. This is manifest in statements involving the conversion of "chemical force" into an "equivalent amount of heat" or of "electrical force," and culminates in the assertion that "Force, like matter, cannot be destroyed."

*The Beauties of Nature, and the Wonders of the World we Live In*. By the Right Hon. Sir John Lubbock, Bart. M.P., F.R.S. (London: Macmillan and Co., 1892.)

So many writers of the present day adopt a pessimistic tone that a pleasant impression is always produced by Sir John Lubbock's genial and imperturbable optimism. In the present volume he undertakes to show how many sources of interest men might find in the world around them, if they would only take the trouble to train themselves to appreciate the scientific significance of ordinary facts. He begins with a study of animal life, and has much that is fresh and suggestive to say about various aspects of the subject. Then there are chapters on plant life, woods and fields, mountains, water, rivers and lakes, the sea, and the starry heavens. The volume is written in the clear, frank style with which all readers of Sir John Lubbock's books are familiar, and it ought

to do much to foster among the class to which he appeals habits of careful and exact observation. His readers have the satisfaction of knowing that of the many things they may learn from him none will afterwards have to be unlearned.

*Algebra for Beginners*. By H. S. Hall and S. R. Knight. (London: Macmillan & Co., 1892.)

THIS work is intended as an "easy introduction" to the author's "Elementary Algebra for Schools," and, besides being treated on lines similar to those of the last-mentioned book, is published in a cheaper form. The idea throughout seems to have been to present the beginner with the practical side of the subject, and with this intention the examples are made as interesting as such examples can be. The usual sequence has not here been strictly adhered to, but a beginner will find that he will still be able to reach the "as far as quadratic equations" limit. It is needless to say that the explanations are stated in clear and simple language, while the examples are all new. That this book will be widely used is undoubted, for it will form an excellent forerunner to the more advanced one referred to above.

*Introduction to Physiological Psychology*. By Dr. Theodor Ziehen. Translated by C. C. van Liew and Dr. Otto Beyer. (London: Swan Sonnenschein and Co., 1892.)

In reviewing the book of which this is a translation (*NATURE*, vol. xlv, p. 145), we pointed out that such a book was badly wanted in English. We are glad, therefore, to welcome a translation of Dr. Ziehen's work, which will serve well as an introduction to the new science of physiological psychology.

### LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of *NATURE*. No notice is taken of anonymous communications.]

#### The Volucella as Examples of Aggressive Mimicry

AN interesting point in the *Volucella* as examples of aggressive mimicry is the fact that they were first used to support the teleological theories of an earlier day, and were subsequently claimed by natural selection. Thus Messrs Kirby and Spence speak of them (Second Edition, 1817, vol. ii, p. 223) as affording "a beautiful instance of the wisdom of Providence in adapting means to their end," and after describing the resemblance of the flies to the bees, they continue, "Thus has the Author of nature provided that they may enter these nests and deposit their eggs undiscovered. Did these intruders venture themselves amongst the humble bees in a less kindred form, their lives would probably pay the forfeit of their presumption." In this theory of Providence it is hard to see where the bees come in. In 1867, A. R. Wallace published an article on "Mimicry and other Protective Resemblances among Animals," which was in 1875 republished in his "Essays on Natural Selection." In this essay (p. 75 of the volume) he spoke of this interpretation as the only case in which an example of mimicry had been "thought to be useful, and to have been designed as a means to a definite and intelligible purpose." He accepts it as a product of natural selection, and since that time it has been constantly used as a well-known example of this principle, so well known, indeed, that the history of it became unnecessary in any publication where space was an object.

I neither originated the principle of aggressive mimicry nor the *Volucella* as examples of it, although I accepted, and still accept, both. Under these circumstances I must, in justice to Kirby and Spence and A. R. Wallace, repudiate the discovery of a significance I should have been proud to have made, but which was made, as a matter of fact, about half a century before I was born. It is only fair to these writers to say this, for Mr. Bateson, although mentioning Kirby and Spence, seems

throughout to give me the sole, or, at any rate, the chief, responsibility for both hypothesis and examples.

In writing my book I made great use of a very interesting series of specimens in the Museum of the Royal College of Surgeons, lately brought together by Prof Stewart. The aggressive mimicry of the *Volucella* was illustrated in one of these cases, and I briefly described the contents of the case in the passage Mr Bateson quotes. I was glad to give a few more details than those supplied by Mr Wallace, and at the same time to mention examples which could be actually seen by readers, for I referred to the collection more than once. I was, however, anxious to obtain confirmation from one who had studied the Hymenoptera and their parasites much more minutely than I had, so I referred the proofs to Mr R C L Perkins, a most observant naturalist, specially interested in these insects. He made some valuable suggestions, but did not modify the account of the case in the Royal College of Surgeons. I think I may claim, therefore, that I took all reasonable precautions to avoid error in a part of the subject which had not then come under my own personal observation. Prof Lloyd Morgan, in his interesting "Animal Life and Intelligence," has also mentioned this example, and figures the *Volucella* and *Bombus muscorum*. He tells me that his figures were copied from a case in the Natural History Museum, so that my selection appears to be supported by the two great biological museums of London.

Within a few weeks of the appearance of my book, I had found out the omission of the other banded humble bees also mimicked by the *mystacea* variety of *Volucella bombylans*, and I showed one of these (I think *B. hortorum*) at a lecture given to the British Association at Leeds in 1890. I had intended, and intend, to repair the omission in any reprint that may be required.

There is, however, nothing inaccurate in the statement that *B. muscorum* is mimicked. We require something more than dogmatic assertions and question-begging metaphor of tabby-cat and fox to establish this as an error of the two museums and the two volumes which have followed them in this respect. Mr Bateson appears to have been studying the literature of *Volucella* rather carefully, if he now extends his investigations to the perfect insects themselves, and compares the individuals in a series of moderate length, he will find that the *mystacea* variety differs much in the demarcation of its rings or zones, and also that the appearance of each individual varies with the direction from which it is observed. The less sharply-marked appearances resemble *B. muscorum*, the likeness being increased by a slight indication of zoning to be seen in the latter.

On July 7 of the present year I captured, in a wood near Newbury, a pair of the variety *mystacea* in copula. The male, the larger insect, was unusually indistinctly zoned. I have submitted the specimens to Mr Verrall who kindly tells me that the large male is certainly the variety *mystacea*, and he evidently thinks there is nothing remarkable about it. On the other hand, the female, which was unusually small, is more interesting, being somewhat an intermediate variety. As Mr Verrall informs me, Rondani has made about a score of intermediate species, this little capture of mine may turn out to be of interest, and it is comforting in a controversy of this kind to be able to add one fresh observation which may be of some use, if only in the way of confirmation.

Now as to the statement, in which no ambiguity was intended, that the two varieties lay in the nests of the bees they respectively mimic. This was, as Mr Bateson says, a very general impression, the impression of naturalists who knew these insects far better than I did, an impression which had already been expressed in the case at the College of Surgeons. If I was mistaken in adopting it, was it not well that I made the mistake, if by its means the general impression should be corrected, having in my book assumed a tangible shape? What man who cares for the advance of science more than for his own advancement would regret to have made a mistake under such circumstances?

But I am not yet satisfied that the impression is not substantially correct. I do not regard the dimorphism of *V. bombylans* as the unique phenomenon it appears to be in the opinion of Mr Bateson. I fail to see any essential biological difference between it and the dimorphism of many Lepidopterous larvae—a dimorphism which extends into the pupal stage of most species of the genus *Sphecia*—or between it and the distinct types into which certain butterflies of the genus *Kallima* can be divided

according to the colouring of the under sides of the wings, or certain moths of the genus *Triphena* according to that of the upper sides of the upper wings. But we know that in those cases which have been tested, while the majority of the offspring resemble the variety to which the parents belonged, a certain proportion follow the other variety, and when the parents belong to different varieties the offspring are more equally divided. It is therefore only to be expected, so far as our present knowledge goes, that both varieties should emerge from the same nest. The important thing to be ascertained, from the point of view of the theory of aggressive mimicry, is not the colour of the offspring which emerge, although this is of high interest on other accounts, but the colour of the parents which enter. It might be supposed that Mr Bateson would have understood this, but it is perhaps too much to expect from a critic who is so aggressively uninterested.

It would be interesting to know the grounds upon which Mr Bateson considers the dimorphism of *V. bombylans* to be almost unique. At present he contents himself with assertions. If we were ever to return to the régime of authority and dogmatism in place of reason and experiment, Mr Bateson's scientific position would be indeed assured.

Years ago I was satisfied that the evidence for the statement in my book was insufficient, and this, too, I had intended to modify when the opportunity occurred. In lecturing I have often alluded to the investigation as an interesting one, and only a fortnight ago suggested it to the members of the Natural History Society at Marlborough College. Two years ago I endeavoured to breed *Volucella* in the manner described by Mr Bateson, I am sorry to say without success. I may therefore claim that the statement quoted by Mr Bateson had produced no paralysis of effort on my part either as regards my own work or that which I have been able to suggest to others.

I may add that the upshot of this inquiry—even if it lead to the conclusion that both varieties lay indiscriminately in the nests of all the species they resemble—would not, in my opinion, remove the *Volucella* from their place as examples of aggressive mimicry, but the working of the principle would be more complex. I do not, however, propose to render myself liable to further sneers about "ingenuity" by discussing it on the present occasion.

Mr Bateson's letter appropriately ends by putting into my mouth a defence I should never have advanced—a defence which was obviously inserted in order to impute discredit—and then proceeding to the easy task of demolishing it. Let me therefore say that a mistake is to me a mistake, whether in a volume intended for the public or a paper presented to a scientific society. Indeed, I regret the former more than the latter. Unfortunately, too, mistakes are more liable to occur in the volume, because the ground is wider, and passes in some directions into less familiar regions. But I can honestly say that I have always done my best to avoid mistakes, and that I correct them as the opportunity arises, in fresh papers or in reprints of volumes. And I derive much comfort from Mr Phelps' dictum, which I am sure appeals to every one who works, that "people who never make mistakes never make anything." EDWARD B. POULTON

Oxford, October 24.

P S—I wish to take this opportunity of correcting certain mistakes in my book ("Colours of Animals," Internat. Sci. Ser.), as it may be some time before the book can be reprinted, owing to the number of copies struck off.

Page 49, 50.—Dr Hurst informs me that my abstract of Weismann's work on seasonal dimorphism is wrong. This will be carefully reconsidered in any reprint.

Page 73.—I wish to withdraw the account of *Phrynocephalus*. Although the structures alluded to are probably alluring, there is not sufficient evidence as to the manner in which they are used.

Page 85.—Professor Howes calls my attention to the description of the nerve-terminations in pigment cells.

Page 94, *et seq.*—Sir J. Ross should be Captain James Ross.

Page 105.—I ought to have added that Mr Sharpe's conclusions are not accepted by Professor Newton.

Pages 142-146.—Mr. Bateson has shown that the white cocoons of *Saturnia* and *Eriogaster* are not due to the white backgrounds employed, but to disturbance of the larvæ. It is still probable that the principle holds in *Haliax prasinana*.

Page 156.—For the above reason I withdraw the argument about the cocoons of *Rumia*, although I believe that it still holds if *H. prasinana* be substituted.

Chapters x, xi should be read in connection with the experiments on Warning Colours since made by Mr. Beddard and published in his volume, "Animal Coloration."

Page 161.—The cockroach is not a good example. As Prof. Weldon pointed out to me, there is no evidence that its unpleasant smell renders it unfit for food. The hive bee would be a better instance.

Page 193, line 7 from bottom—*Fibrous* should be *subulous*.

Page 203, line 6 from bottom—For *suited* for read *bearing*.

Page 208, line 13 from top—*Direct* should be *direct*.

Page 224.—I have since heard from Mr. Skeritchly that he did not intend the argument which I quote at the bottom of the page to be taken seriously.

Page 236—*Diadema bolina* should be *D. missippus*, and it and the *Danais* it mimics occur in three varieties, not in two. I owe this to Col. Swinhoe, the error was copied from Trimen. E. B. P.

### The Geology of the Asiatic Loess

In the spring and early summer of this year I had the opportunity, in company with Mr. S. B. J. Skeritchly, of examining closely the loess deposits of Shantung, stretching from Chefoo to Taiman, the provincial capital.

The investigation convinced us both that the original loess of China must be regarded as a marine deposit. Subsequent to the time of Mr. Skeritchly's leaving the province, on June 17, I was able to supplement these conclusions by the discovery of a band of limestone rocks bored by pholades and crustaceans up to a height of about 1100 feet, above which line no indications of late marine action were visible. The rocks in the locality near Tsinan fu are carboniferous limestones interbedded with dioritic porphyries, and are still horizontal and unbroken for some thousands of square miles, having received their present contour in pre-loess ages. The dip for hundreds of square miles in this locality seldom exceeds from 2° to 8°. These facts we hope to make the subject of a joint memoir.

The loess of China has, however, been traced almost continuously beyond the limits of the eighteen provinces to the foot of the Pamirs. West of the Pamirs loess occurs in the valley of the upper Oxus, probably in the Kizil Kum, and up to the Caspian, and its marine origin requires us to believe in the submergence within late geologic time of the greater part of Central Asia. Most geologists recoil at such a suggestion, and I am in a small minority in accepting the view that the present distribution of ocean and continent is of very recent date. I may, however, in condonation of heterodox views, refer to the position of the argument with regard to the alleged shifting of the terrestrial axis of rotation, which has within the last few years entered on a new phase. When some years ago I presented these views to the Council of the Geological Society of London they were scouted as utterly untenable. Since that time, while English astronomers have held the view that practically the axis of rotation has undergone, within the limits of observation, no change, American astronomers have come to the conclusion that a secular movement is actually in progress. My own geological observations in Europe, North America, and Asia have led me to infer that the North Pole has within recent geological time shifted, and that a shift is in all probability in progress at the present time along a line following approximately the direction of the 70th meridian of west longitude. This shift is not to be taken to involve a change in the direction in celestial space, but is rather a rolling of the earth over its axis, the latter remaining practically stationary.

Dynamical causes sufficient to account for the change of position of the terrestrial poles, and in consequence of the parallels of latitude, seem to me to be at work. Prof. G. Darwin has calculated the probable change in the position of the pole due to an elevation of the bed of the Pacific Ocean, but no one has touched the converse effect of the change of the pole on the relative levels of the oceans and continents. In addition to the cause suggested in the possible elevation of large tracts of continental land, there are other influences at work tending in the same direction. The different distribution of the large masses of ice around the poles, which probably varies within somewhat large limits, and the slow disturbance of equilibrium re-

sulting from the growth of deltas and deep sea deposits, have frequently been adduced. More important still is perhaps the differential influence of tidal friction in retarding the rotation, the effect of which must be sensibly unequal in the two hemispheres north and south of the equator, another cause may be looked for in the action of aerial currents, the effect of which in the northern hemisphere as containing greater masses of elevated land must be greater.

Another potential cause of shifting has never, that I am aware of, been formulated. Although at present of comparatively small influence, it must at various geological periods have been of great importance. It leads on to dynamic considerations of tidal energy beyond the compass of a letter to explain. The relative part played by the sun and moon, as deduced from gravitational formulæ, does not quite agree with the observed phenomena of our daily tides. It is believed by many that the ordinary lunar tide, affecting mainly the oceanic envelope, is complicated by the presence of a terrene tide largely influenced by the sun, and that the earth does to an appreciable extent yield twice in the twenty-four hours to the deforming force of solar gravitation. So long as this oscillation takes place at regularly recurrent intervals no energy is wasted. Should, however, a sudden snap occur, breaking the rhythm of the oscillation, some energy is evidently spent, and this can only be made up from the *vis viva* of rotation. Such snaps do occur occasionally, the regular oscillation is momentarily suspended, and the waters of the ocean rush in to restore the equilibrium. This is the well-known "tidal" wave that so frequently occurs in connection with earthquakes.

Such a snap on the equatorial line would simply retard the rotational period generally. North or south of this line, as the moments of rotation would be instantly unequal, the sphere would roll over its axis of rotation, and a shift in the position of the poles occur. The earth is not a perfectly rigid mass. Were it as rigid as steel, the interior within a depth of 200 miles would yet, under the pressure of gravitation, behave as a liquid, a shift in the pole would then be met either by a corresponding shift in the equatorial protuberance, or a change in the ocean level, or, more probably, by a compound action of both. In the latter case, to fulfil the conditions of equilibrium, the ocean surface in the neighbourhood of the new equator would rise, and if the shift were sufficiently great, would overflow the lowlands. If the equator, in the longitude of Central Asia, had at any former time passed north of its present position, and the rock masses of the Continent had not been elevated, a mid-Asian sea must have resulted. The undisturbed position of the carboniferous rocks, and the plain evidence that the surface sculpturing of the rocks was of pre-loess age, show that the process was unaccompanied by violent movements.

The theory of the shift of the earth over its momentary axis accounts better than any other for the geological condition of polar lands, and I venture to state it again in brief, as on this occasion the initiative has come from the astronomers, not the geologists.

THOS. W. KINGSMILL

Shanghai, China, August 20.

### Note on Mr. Kingsmill's paper

I think it will be difficult for Mr. Kingsmill to adduce evidence of geological changes large enough to produce any considerable shifting of the position of the principal axes of the earth, and accordingly I should feel sceptical as to a theory which postulates that such change has been sufficient to explain considerable changes of climate.

With respect to a later part of the paper, I am entirely at variance with his views. As far as I know "the relative part played by the sun and moon" in producing oceanic tides is in exact accordance with gravitational formulæ.

The existence of a terrene tide is a matter of speculation, but, as the earth cannot be perfectly rigid, it must exist to some extent. The amplitude of the lunar terrene tide must certainly bear to that of the solar the same ratio that holds in the case of oceanic tides, and there is no reason, that I know of, for attributing a greater efficiency to solar action in the case of the deformation of the solid portion of the earth.

I am quite unable to follow the argument by which the so-called "tidal" wave produced by earthquake shock is supposed to produce a retardation of the earth's rotation.

## Optical Illusions.

REFERRING to the article in NATURE for October 20, may I mention a rather common optical illusion which I do not remember to have yet seen in print. If a gothic arch is unequally divided by a space between two vertical parallel lines, these lines will not only seem to diverge slightly where they intersect the lines of the arch, but the arch itself is caused to appear as if one half had slipped bodily down from the other to an extent

equal to its own thickness. In the figure given above it is impossible to believe that but for the intervention of the vertical interlinear space the two halves would be seen to meet perfectly with the apex at A. This illusion is worth the notice of architects who desire to avoid the disquieting effect upon the eyes of observant persons which is produced by the intersection of the chancel arch of a church by an intervening pillar.

## A Remarkable Rainfall.

THE rainfall here of October has been so remarkable that it seems worth while to place it on record in your columns. Rain fell on twenty-five days during the month, making a total fall of 10 3/4 inches. As the annual rainfall on an average of eleven years is 31 10 inches, it will be seen that very nearly one-third of this amount fell in one month. This is by far the highest amount I have recorded since I began to make records in January, 1878, the next highest month being August, 1879. On that occasion five inches fell in thirty hours on the 17th and 18th, and many bridges were carried away in Flintshire and Denbighshire, but the total fall for the month was only 7 8/9 inches. Dr. Nicol, of Llandudno (six miles from here), who has registered the rainfall since, and including 1861, informs me that it amounted last month to 8 5/6 inches there, this also being the highest month he has ever recorded.

In September rain fell on twenty-three days, and though the total fall was only 3 7/7 inches, yet the constant rain, combined with an unusually low temperature (the mean maximum being only 56° 6, and the highest shade temperature 67° 4, against 64° 6 and 81° 2 respectively in 1891), made it almost impossible to get in the harvest.

ALFRED O. WALKER.

Nant-y-Glyn, Colwyn Bay, November 5.

## On a Supposed New Species of Earthworm and on the Nomenclature of Earthworms.

IN yesterday's NATURE I find that the Rev. Hilderic Friend has again given the name *L. rubescens* (Friend) to a supposed new species of earthworm. This worm appears to me to be identical with *Entorion festuorum* (Savigny), described under the name *Lumbricus festuorum* by Rosa. Though comparatively rare, it is by no means new, nor even new to Britain, though I know of no published record of its occurrence here. I met with two or three specimens among the worms supplied to me when I was working at the chapter on Lumbricus in "Marshall and Hurst," and identified them subsequently by the help of Rosa's table. At the time I took them for mere varieties, and put them

into a bottle for future study. I believe the specimens are now in the possession of Dr. Benham, who has entirely overlooked the species in his "Attempt to Classify Earthworms" (*Quart. Journ. Micr. Sci.* xxxi).

The specific name *terrestris* must also, it appears to me, be dropped. Linnaeus did not define a species under that name, but applied it to what are now universally regarded as several distinct species. The species so called by Mr. Friend was, I believe, first defined by Savigny under the name *Entorion herculeum*. The diagnostic characters of the species are given by Rosa in his useful table of the species ("I Lumbricidi dei Piemonte," p. 25), and he calls it *Lumbricus herculeus*, to which name the usual rules of nomenclature bind us.

I would therefore suggest the following alterations in Mr. Friend's "Chart of the Genus Lumbricus" —

1 For "*Terrestris* (Linn.," read "*herculeus* (Sav.)"

2 For "*Rubescens* (Friend)" read "*festuorum* (Sav.)"

Owens College, October 28. C. HERBERT HURST

## Ice Crystals

DURING the cutting of the formation for a railway I observed on Tuesday morning, the 18th inst., a peculiar series of ice crystals. The ground is composed of arenaceous clay largely mixed with sand and small gravel, and is of a very open nature, the surface being covered with moorland grass, rushes, and coarse ferns. These crystals were only found in a length of about nine feet, the ground on both sides of the patch being hard frozen.

These crystals were acicular, and sprang from a base of very porous opaque ice, but every needle was entirely free and distinct throughout its height, and at first sight appeared to be bound together with two bands, one at one third and the other at two thirds of the height. A closer examination proved that the band appearance was due to a slight enlargement of the crystals at these points, the ice being opaque, whilst the needles were perfectly translucent.

The average height of these crystals was about one inch, the needles having a diameter of about 1/4th part of an inch, and were grouped together in clusters of forty or fifty, forming an irregular square of about 1/2-inch on the side. Some of these crystals were growing vertically from the ground, others springing out horizontally from the side of the cutting, and were either straight, curved, or bent round forming a half circle. This morning the same form of crystals existed, but were much larger, being fully two inches long. On both occasions the air was calm and clear, the min. ther. reading 30° on the 18th, and 24° to day.

Leamington, October 25.

## Lunar Craters

THE letter and illustration offering a suggestion as to the formation of lunar craters remind me of an experiment I once saw during a chemical lecture, bringing out the same point very clearly.

A shallow dish containing a layer of damp sand, 1/2", was flooded with a 1-inch coating of Paris plaster, of the consistence of cream, and the dish set to dry over a Bunsen flame.

As the plaster set, the surface was pitted with crater-like holes, formed by the escape of steam from the sand at the bottom of the dish, giving a perfect representation of a lunar surface.

As some of your readers might care to try this experiment, I take the liberty of sending you this "recollection."

## A Fork-tailed Petrel.

THE occurrence of a Fork-tailed Petrel as far inland as Macclesfield may perhaps interest some of the readers of NATURE.

It was picked up by a man on the 11th ult., two days after the stranding of the *Sirene* in a gale at Blackpool, and being unacquainted with the species he sent it to me as a curiosity. I identified it as a Fork-tailed Petrel, and Mr. J. H. Salter, of Aberystwyth College, has kindly confirmed this decision.

Some of the feathers on the forehead are tipped with white. Does this indicate a young bird, as I can find no mention of it in any of the plumage descriptions that I have seen?

NEWMAN NEAVE.

Rainow, near Macclesfield, November 5.

foreign to our subject I shall be able to show, however, that this is not so

*In primis* we must remember that it is a question of Silsilis, where we know both from tradition and geological evidence, in ancient times the first cataract was encountered. The phrase "The Nile emerges from its fountains" would be much more applicable to Silsilis, the seat of a cataract than as it is at present. We do not know when the river made its way through this impediment, but we do know that after it took place and the Nile stream was cleared as far as the cataract that still remains at Elephantine, a Nilometer was erected there and that during the whole of later Egyptian history at all events the time of the rise of the river has been carefully recorded both there and at Rhoda.

From this it is fair to infer that in those more ancient times the same thing took place at Silsilis, if this were so the reason of the record of the coming of the inundation at Silsilis is not far to seek, and hence the suggestion lies on the surface that the records in question may state the date of the arrival *in relation to Memphis time*.

So far in my inquiries I have not been able to find a complete discussion of the influence upon local calendars, in different parts of the Nile valley, of the variations of the phenomena upon which the Egyptians depended for the marking of New Year's day.

If the *solstice* had been taken alone, the date of it would have been the same for all parts of the valley, but certainly the *solstice* was not taken alone, and for the obvious reason that they wanted something to warn them of the Nile rise, and in the lower reaches of the river the rise precedes the *solstice*.

Nor was the heliacal rising of Sirius taken alone.

As we have seen, according to Biot the heliacal rising of Sirius at the *solstice* took place on July 20 (Julian) in the year 3285 B.C., and according to Oppolzer, it took place on July 18 (Julian) in the year 3000  $\pm$  B.C.

But this is too general a statement, and it must be modified here. There was a difference of 7 days in the date of the heliacal rising, according to the latitude, from southern Elephantine and Philæ, where the heliacal rising at the *solstice* was noted first, to northern Bubastis. There was a difference of four days between Memphis and Thebes, so that the connection between the heliacal rising and the *solstice* depended simply upon the latitude of the place. The further south, the earlier the coincidence occurred.

Here we have an *astronomical* reason for the variation in the date of New Year's day.

But it was chiefly a question of the arrival of the Nile flood, and the date of the commencement of the Nile flood was by no means common to all parts of Egypt.

I cannot find any statement of the dates of the arrival of any one Nile flood at places between Elephantine and Cairo. Dr. Wallis Budge<sup>1</sup> states "The indications of the rise of the river may be seen at the cataracts as early as the end of May."

Now if we take the 1st cataract to be here meant, and deal with May 31, since the average day of arrival of the inundation at Cairo is 3 days after the *solstice*—that is June 20 (Greg.)—we have 24 days for the flood-travel for the 600 miles between Elephantine and Cairo, four-fifths of a month elapsing between the times at which the Green Nile colours the pool at Syene below the Cataracts, and the river at Memphis; so that the further south, the earlier the flood was noted. This gives us about a mile an hour. This certainly seems too slow.

But if we assume 16 days, this would give us about 15 days between Silsilis and Cairo, and 12 days between Thebes and Cairo, taking Cairo to represent the ancient Memphis. Now this represented a difference in the new year's days of different places, compared to which our

modern differences of local time sink into insignificance, for they only touch hours of the day, and the reason that I have referred to them here is to point out that if the assumption made is anything like accurate, if, for instance, in Pepi's time a Nile rise were observed at Silsilis, there might easily be a difference of 15 days between the rise of the Nile at Silsilis and the Memphis 1st of Thoth. If both at Silsilis and Memphis the Nile rise marked 1st Thoth, the day of the rise at Memphis would correspond to 15th Thoth at Silsilis, so that a king reaching Silsilis with Memphis local time, would be struck with this difference, and anxious to record it, may not this then have been the important datum recorded in the sacred books? If so, it would not touch the question of the fixed or vague year at all.

Let it, then, be for the present conceded that there was a vague year, and that at least some of the inscriptions which suggest the use of only a fixed year in these early times may be explained in another way. I do not say the above explanation is the correct one, for the assumption of 16 days may be wrong, even if difference in the dates of the heliacal rising at the two places be taken into account.

The dates we have found—trying to take the very simplest way of writing a calendar in pre-temple times, and using the calendar inscriptions in the most natural way—are for the coincidence of the heliacal rising of Sirius at, or near, the *solstice*—

270 B.C.  
1728 B.C.  
3192 B.C.

Now here we meet with a difficulty which, if it cannot be explained, evidently proves that the Egyptians did not

FIG. 6.—Julian dates of the 1st of Thoth (vague) from 23 A.D. to 240 A.D.

construct and use their calendar in the way we have supposed.

We have it on the authority of Censorinus that a Sothic period was completed in 139 A.D., and that there was then a vague year in partial use. It is here that the work of Oppolzer is of such high value to us. He discussed all the statements made by Censorinus, and comes to the conclusion that his account is to be depended upon. It

<sup>1</sup> "The Nile," p. 46

has followed from the inquiries of chronologists that in this year the 1st of Thoth took place on July 20 (Julian), the date originally of the heliacal rising of Sirius, the beginning of the year.

This being so, then, in the year 23 A.D.—in which the Alexandrine reform of the calendar, of which more presently, was introduced—the 1st of Thoth would take place on August 29, a very important date. Censorinus also said that in his own time (A.D. 238) the 1st of Thoth of the vague year fell on June 25. Fig. 5 will show the connection of these three dates in reference to the vague year. The relations of the statements made as to the years 139 and 238 are very clearly discussed by Dr. Oppolzer.

Oppolzer, then, being satisfied as to the justice of taking the year 139 A.D. as a time of coincidence of the fixed and vague years—the latter being determined alone by the heliacal rising of Sirius, and, be it remembered, not by the solstices—calculated with great fulness, using Leverrier's modern values, the years in which, in the various Egyptian latitudes, chiefly taking Memphis (lat. 30°) and Thebes (lat. 25°), the coincidence between the two Thoths occurred in the previous periods of Egyptian history. He finds these dates for latitude 30° as follow—

	Julian year	Historical year <sup>1</sup>
0	- 4235	4236
1	- 2774	2775
2	- 1316	1317
3	+ 139	139
4	+ 1591	1591
5	+ 3039	3039

Now the date which Oppolzer gives for the coincidence which is nearest the date we had previously determined at 270 B.C. is 139 A.D. There is a difference of 409 years.

The question is, Can this fundamental difference be explained? I think it can.

In the first place, it is beyond doubt that, in the interval between the Ramessids and the Ptolemies, the calendar, even supposing the vague year to have been used and to have been retained, had been fundamentally altered, and the meanings of the hieroglyphics of the tetramenes had been changed—in other words, the designations of the three seasons had been changed.

On this point I quote Krall in a note.<sup>2</sup>

<sup>1</sup> It should be observed that a distinction is made between the Julian and the historical year. This comes from the fact that when astronomical phenomena are calculated for dates A.C., it must be remembered that chronologists are in the habit of designating by 1, or rather by -1, the first year which precedes the instant of time at which the chronological year commenced, while astronomers mark this year in their tables by 0. It follows, therefore, that the rank of any year B.C. is always marked by an additional unit in the chronological dates. For the Christian era, of course, chronologists and astronomers work in the same way. The following table, given by Biot, exhibits the connection between these two methods. In the latter Biot shows the leap-years marked R, and the corresponding years in the Scaligerian chronological period are also given.

Dates of Julian Years commencing on January 1			
According to Chronologists.		According to Astronomers	Corresponding years of the period of Scaliger
-6	...	-5	4708
-5B	...	-4B	4709
-4	...	-3	4710
-3	...	-2	4711
-2	...	-1	4712
-1B	...	0B	4713B
Physical instant when the era commenced			
+1	...	+1	4714
+2	...	+2	4715
+3	...	+3	4716
+4B	...	+4B	4717B
+5	...	+5	4718

<sup>2</sup> *Loc. cit.* p. 29. "It is well known that the interpretation of the seasons and the months given by Champollion was opposed by Brugsch, who propounded another, which is now universally adopted by experts. Something has happened here which is often repeated in the course of Egyptian history—the signs have changed their meaning. Under the circumstance that the vague year during 1461 years wanders through the seasons in a great cycle, it

The three hieroglyphic signs used for the tetramenes are supposed to represent water, flowers, and a barn, and the natural order would be that the first should represent the inundation, the second the sowing which succeeds it, and the last harvest time. If this be conceded, the initial system would have had the month Thoth connected with the water sign, as Thoth in early Egyptian times was the first inundation month. But in the times of the Ramessids even this is not so. Thoth has the sowing sign assigned to it. In the time of the Ptolemies the flood is no longer in Thoth, but in Pachons, and Pachons has the barn sign attached to it, while the month Thoth is marked by the water sign, thereby bringing back the hypothetical relation between the name of the month and the sign, although, as we have seen, Thoth is no longer the flood month.

Egyptologists declare that all or at least part of this change took place between the periods named, they are undoubtedly justified as regards a part.

At one point in this interval we are fortunately supplied with some precise information. In the year 238 B.C. a famous decree was published, variously called the decree of Canopus and the decree of Tanis, since it was inscribed on a stone found there.

It is perfectly clear that one of the functions of this decree was to change, or to approve an already made change in, the designation of the season or tetramene in which the inundation commenced, from Thoth to Pachons.

Another function was to establish a fixed year, as we shall see presently. We must assume then that a vague year was in vogue prior to the decree. Now the decree tells us that at its date the heliacal rising of Sirius took place on 1 Payni. Assuming that this date had any relation to the system we have been considering, the cycle to which it belonged must have begun

Days  
5 Epacts  
30 Mesori  
30 Epiphi  
30 Payni

$95 \times 4 = 380$  years previously, that is, in the year 618 B.C.

Now here at first sight it would seem that the Sothic cycles we have been considering have no relation to the one now in question; for, according to my view, the last Sothic cycle began in 1728 B.C.

A little consideration, however, will lead to the contrary view, and show that the time about 600 B.C. was very convenient for a revision of the calendar.

In the first place nearly a month now elapsed between the coming of the flood and the heliacal rising, and in the second, by making the year for the future to begin with the flood, a change might be made involving tetramenes only.

Thus, commencement of cycle	1728 B.C.
Epacts	5
Two tetramenes	240
Month between flood and rising of Sirius	30 <sup>1</sup>
	$275 \times 4 = 1100$
	628 B.C.

Nor is this all. A very simple diagrammatic statement will show what might also have happened about 618 B.C.

It is natural that the signs for the tetramenes should have changed their significations in the course of millenniums.

<sup>1</sup> While Thoth was the first month of the inundation in the documents of the Thutmosids and Ramessids, we have in the time of the Ptolemies the month Pachons as the first month of the flood season. While Brugsch's explanation is valid for the time of the Ramessids, it is not so for that of the Ptolemies, to which Champollion's view is applicable.

<sup>2</sup> Probably too great a value by 2 or 3 days.

if a reformer of the calendar (and one especially of conservative tendencies) appeared upon the scene, who believed that the ancient sign for the inundation-tetramene was the water sign, and that the ancient name was Thoth. Finding the cycle beginning in 1728 with the signs as shown—

when starting fresh, he would seize the opportunity of effecting a change, not only by dealing with a tetramene, but he would change the names of the tetramenes allocated to the signs

As Krall remarks, it was almost merely a question of a change of the sign! It really was more, because the new tetramene began with the flood

Assuming this, we can see exactly what was done in 238 B C, i.e. about 380 years later. We have seen that the 380 years is made up of

$$\begin{aligned} &5 \text{ Epacts} \\ &30 \text{ Mesori} \\ &30 \text{ Epiphi} \\ &30 \text{ Payni} \\ &— \\ &95 \times 4 = 380 \end{aligned}$$

the heliacal rising of Sirius occurring on 1 Payni, having swept backwards along the months in the manner already explained. We had then—

To sum up, so far as we have gone we have the three inscriptions at Philæ, Elephantine, and the still more ancient one of Pepi, indicating on the simple system we have suggested beginnings of Sothic cycles on the 1st Thoth about the years

$$\begin{aligned} &270 \\ &1728 \\ &3192 \end{aligned} \left. \vphantom{\begin{aligned} &270 \\ &1728 \\ &3192 \end{aligned}} \right\} \text{B C}$$

On the other hand, we have the decree of Canopus, giving us by exactly the same system a local revision of the Calendar about 600 B C. I say about 600 B C because it must be remembered that a difference of  $2\frac{1}{2}$  days in the phenomena observed will make a difference of 10 years in the date, and we do not know in what part of the valley the revision took place, and therefore at what precise time in relation to the heliacal rising the Nile-rise was observed

Whenever presumably it took place, New Year's day was reckoned by the Flood, and the rising of Sirius followed nearly, if not quite, a month afterwards. The equivalent of the old 1st Thoth was therefore 1 Payni. In months, then, the old 1st Thoth was separated from the new one (= 1 Payni) by 3 months (Payni, Mesori, Epiphi) and the Epacts.

In this way, then, we can exactly account for the difference of 409 years referred to above as the dates

assigned by Censorinus and myself for the beginning of the Sirius cycle

$$\begin{aligned} \text{Difference between 270 and 239} &= 31 \text{ years} \\ 3 \text{ months} &= 90 \text{ days} \times 4 = 360 \text{ „} \\ 5 \text{ epacts} \times 4 &= 20 \text{ „} \\ &411 \text{ „} \end{aligned}$$

The difference of two years is equal only to half a day!

It seems, then, pretty clear from this that the suggestion I have ventured to make on astronomical grounds may be worth consideration on the part of Egyptologists. If our inquiries have really led us to the true beginnings of the Sothic periods, it is clear that those who informed Censorinus that the year 139 A D was the end of a cycle omitted to tell him what we now can learn from the decree of Tanis

J NORMAN LOCKYER

(To be continued)

### TECHNOLOGICAL EXAMINATIONS

THE report of the results of the Technological Examinations, held this year under the direction of the City and Guilds of London Institute, has a special interest, seeing that after this year the system of payment on results in connection with all classes outside the Metropolis will be discontinued. There is no doubt that the offer of payment to teachers helped very greatly in 1879 to stimulate the formation of technical, as distinct from science, classes, and the great extension of this work of the Institute is largely due to the offer then wisely made of contributing towards the cost of instruction. The tables furnished in the report, and the diagram of results, are very interesting as showing the great development of these trade classes. Since 1880 the number of candidates for examination has increased more than tenfold, the numbers being 816 in 1880 and 8,534 in 1892. In 1885 there were 263 technological classes in different parts of the country, and in the session 1891-2 this number had increased to 610. There is, of course, a corresponding increase in the number of students in attendance at these classes. In 1881 the number of students was 2,500, this year it was 16,565. This record of progress is certainly satisfactory, and particularly so, seeing that prior to 1891 there was no sort of organization to carry on the work of directing and assisting technical classes for artisans in different parts of the country. As a pioneer movement, the work of the City Guilds Institute has been eminently successful, and many of the Technical Schools which have now been brought under the control of County Councils undoubtedly owe their origin to the technological classes promoted by the City Guilds. The question now demanding attention is the future of these classes. Much is to be said in favour of associating them more closely with the science classes, which are held in the same schools, but what is wanted for the permanent improvement of such classes is a system of efficient inspection by persons competent to advise County Councils with respect to the important work now under their control.

From the report and programme it appears that year by year the Institute adds to the extent and efficiency of its examinations by the introduction of new subjects and of practical tests. Practical examinations were held this year for the first time in photography, goldsmiths' work, boot and shoe manufacture, and in wood-working in connection with the examination in manual training for teachers of public elementary schools. This last examination is somewhat different in kind from the other examinations of the Institute. It is not a trade examination. Its purpose seems to be to encourage instruction of a distinctly educational character. Moreover, it is a

close examination. None but teachers of public elementary schools are eligible, and these must have regularly attended a course of practical lessons in a registered class under a teacher approved by the Institute. Notwithstanding these restrictions, 615 candidates presented themselves at the first examination held by the Institute, and of these 350 passed, 195 obtaining the Teacher's Certificate.

The report contains full statistics of the results of the examinations in each of the 61 subjects included in the programme, and it also shows the results in each of the 210 towns where the examinations were held. Of the centres outside London, Manchester sent up the largest number of successful candidates, whilst Glasgow, Dundee, and Leeds come next in order. The report calls attention to the fact that the proportion of candidates to the population is far less in London than in Manchester, whilst the hope is expressed that the larger facilities for technical instruction which will be available within the next few years will lead to an increase in the number of students and of candidates for examination. This increase will no doubt take place with the opening of new polytechnic institutions, but we venture to think that the real improvement in technical education cannot be correctly measured by any mere increase in the number of candidates for examination. It depends much more upon the character and quality of the instruction which the candidates receive. The great defect of our present organization is the poverty in knowledge and practical experience of the teachers of our science and technical classes. Some improvement in the qualifications of teachers, and in the conditions of their training, is needed before progress can be measured by the increase in the number of students in attendance, or of candidates for examination.

We notice that in future the Institute proposes to award two kinds of certificates—the one kind to students who have regularly attended a course of instruction under an approved teacher, and the other to candidates who may present themselves for examination without giving any evidence as to their training. In this way the Institute proposes to combine the functions of a teaching and an examining body. The certificate indicating that the candidate has received some training at a school of recognized position will doubtless acquire a distinct value, but much will depend upon the ability and the reputation of the teacher under whom the candidate may have studied.

Of the many alterations in the new programme the most important is the addition of a practical part to the examination in mechanical engineering. This examination of the Institute has never seemed to us wholly satisfactory, as overlapping, to too great an extent, the examinations of the Science and Art Department in applied mechanics, machine construction, and steam. But in future the examination will consist of two parts, one of which will be distinctly specialized with a view to the candidate's occupation. Moreover, in the honours grade, candidates will be required to undergo a practical examination in either machine designing or workshop practice. At the last examination in this subject 966 candidates presented themselves, of whom 536 passed. It is satisfactory to note the continuous increase in the number of candidates. In plumbers' work, a trade in the successful practice of which every householder is interested. In this subject a high standard for passing is wisely maintained. Of the 816 candidates who presented themselves, 235 came up for the practical part of the examination, and of these only 85 succeeded in passing in both parts of the examination, and are qualified for certificates.

There is little doubt that the statistics furnished in this report go far to show that a high value is attached by artisans and their employers to the Institute's certi-

icates, and that the progress of technical education has been advanced by the cautious and judicious manner in which the Institute has conducted this department of its operations.

#### ROBERT GRANT.

IN Robert Grant, who at the ripe age of seventy-eight died at the place of his birth, Grantown-on-Spey, on October 24, 1892, science loses one of her ablest historians. His education was interrupted by a serious illness, which confined him to his bed from his fourteenth to his twentieth year. With surprising energy, however, on his recovery he set about the study of mathematics and the acquisition of ancient and modern languages. After studying for a time at King's College, Aberdeen, he went to London to collect materials for a history of physical astronomy. Thence he proceeded to Paris in 1845, where for two years he attended the lectures of Arago at the Observatory, and those of Leverrier and others at the Sorbonne. Returning to London, he lost little time in beginning the great work with which his name will always be associated. It was published in numbers, the first of which appeared in September, 1848, but it was not until March, 1852, that the whole work was issued. It bears the title "History of Physical Astronomy from the Earliest Ages to the Middle of the Nineteenth Century, comprehending a detailed account of the establishment of the Theory of Gravitation by Newton, and its development by his successors, with an exposition of the progress of research in all the other subjects of Celestial Physics." Most completely do the contents of the volume fulfil every expectation raised by this comprehensive programme. The fame of its author was at once established. Four years later he received from the hands of the late Mr. Manuel J. Johnson, President of the Royal Astronomical Society, the gold medal, then for the first time awarded for literary service to astronomical science. One paragraph of the address delivered on that occasion may here be quoted as characterizing most justly the work as well as its author: "Throughout the book no one can fail to be struck with the rare skill, integrity, and discernment the author has displayed in tracing the successive stages of progress, or with the scrupulous care he has taken to assign to each of the great men whom he reviews their proper share in the common labour. Nowhere is this more conspicuous than in the discussion relative to the discovery of the planet Neptune. By a simple narration of facts he has placed the history of that great event in so clear and so true a light, that I believe I am not wrong in saying he has gained an author's highest praise under such circumstances—the approval of both the eminent persons concerned." Even now, forty years after its publication, the "History" has lost none of its value as a mine of information, and as a delightful guide to those who desire to make a closer acquaintance with the astronomers of the past, as well as their works.

For some time Mr. Grant edited the "Monthly Notices" of the Royal Astronomical Society, and was a member of their Council. In conjunction with the late Admiral Smyth, he translated and edited Arago's "Popular Astronomy" (2 vols. 1855 and 1858). Meanwhile his health had so far improved that in 1858 he was able to go through a course of observational astronomy at Greenwich Observatory. In the following year, on the death of Prof. J. Pringle Nichol, he was appointed Professor of Astronomy, and director of the Observatory in the University of Glasgow.

As a member of the party that went to Spain in the troop-ship *Himalaya*, to observe the total solar eclipse of July 18, 1860, Prof. Grant, from his station near Vittoria, had the satisfaction of seeing a portion of the chromosphere, the existence of which as a thin layer en-

veloping the photosphere he had abundantly demonstrated in the winter of 1850-51, from a discussion of all the observations extant ("History," pp 395, 396). It can excite no surprise that Prof Grant assumed the red layer and also the prominences to shine by reflected light, when it is recollected that the sun's light and heat were then supposed to originate wholly in the photosphere while the nucleus was thought to be so cool as possibly to be habitable. When Prof Grant took charge of the Glasgow Observatory the only useful instrument he found was the transit-circle by Ertel and Son, of Munich, but through the liberality of a few friends, chiefly in Glasgow, a nine-inch Cooke Equatorial was added to the Observatory some years afterwards. After thoroughly testing the transit-circle the new director commenced a series of observations of Mercury, Neptune, the minor planets, and a selection of stars from the British Association Catalogue. Gradually, however, his attention was concentrated entirely on the stars the list being correspondingly expanded. The observations of planets were communicated from time to time to the *Astronomische Nachrichten* or to the "Monthly Notices."

The stellar observations were published at the expense of her Majesty's Government in 1883 in the well-known "Catalogue of 6415 Stars for the epoch 1870, deduced from Observations made at the Glasgow University Observatory during the years 1860 to 1881, preceded by a Synopsis of the Annual Results of each Star arranged in the order of Right Ascension."

In the introduction will be found a discussion of the Proper Motions of 99 stars. A very complete and appreciative review of this work from the pen of Prof Auwers of Berlin appeared in the *Vierteljahrsschrift der Astronomischen Gesellschaft* (19 Jahrgang). The Glasgow star places were at once looked on with confidence by the numerous observers of comets and minor planets. One point connected with the Catalogue deserves special mention, viz that, although the observations from which it is derived extend over a space of twenty-one years, the work appeared within two years of the close of the series. This promptitude excites the greater admiration when we learn that, exclusive of Prof Grant's personal share in the work, no less than thirteen young assistants at various times took part in the observations, and two others in the computations. Many of these personal changes, each of which brought its quota of extra work to Prof Grant, were no doubt in some measure due to the smallness of the allowance provided for assistance, viz £100 per annum. Prof. Grant, however, was the last man to waste his energies in useless complaint, and dismisses this point with the remark that "in recent years the work of scrutinizing, reducing to a common epoch, and combining together the vast mass of the observations of the catalogue, extending over a period of more than twenty-one years, has pressed very heavily upon the slender resources of the observatory." The important time service of the City of Glasgow was originated by Prof Grant some thirty years ago, and continues in operation up to the present moment. In 1855 he received from the University of Aberdeen the degree of M.A., followed by that of the honorary LL.D in 1865, in which latter year he was elected a Fellow of the Royal Society of London. For three years he presided over the Philosophical Society of Glasgow, to whose proceedings he made various contributions. It may also be noted that among his writings are two remarkable letters proving beyond a shadow of a doubt the spurious character of the pretended Pascal correspondence. These letters were printed in the *Comptes Rendus* by special permission of the French Academy.

In manner Prof. Grant was singularly vivacious, and to the last he greeted with the warmest enthusiasm every fresh discovery in the science to which his life was devoted.

R. C.

## NOTES

THE following is the list of names recommended by the President and Council of the Royal Society for election into the Council for the year 1893. The ballot will take place at the anniversary meeting on November 30.—President, The Lord Kelvin, D.C.L., LL.D., treasurer, Sir John Evans, K.C.B., D.C.L., LL.D., secretaries, Prof Michael Foster, The Lord Rayleigh, D.C.L., foreign secretary, Sir Archibald Geikie, LL.D., other members of the Council, Captain William de Wiveleslie Abney, C.B., Sir Benjamin Baker, K.C.M.G., LL.D., Prof Isaac Bayley Balfour, William Thomas Blanford, Prof George Carey Foster, Richard Tetley Glazebrook, Frederick Ducane Godman, John Hopkinson, Prof Joseph Norman Lockyer, F.R.S., Prof. John Gray McKendrick, William Davidson Niven, William Henry Perkin, LL.D., Rev Prof B. Price, The Marquess of Salisbury, K.G., Adam Sedgwick, Prof William Augustus Tilden.

AN international subscription for a testimonial to M. Pasteur on the occasion of his seventieth birthday on December 27 is to be opened by the French Academy of Science. Many men of science in all parts of the world will be glad to have this opportunity of expressing their high appreciation of M. Pasteur's labours.

SOME time ago we announced that Baron Nordenskiöld proposed to edit a number of very remarkable letters and memoirs of Carl Wilhelm Scheele, who died in 1786. It has now been decided that the one hundred and fiftieth anniversary of the birth of this great Swedish chemist, on December 9, shall be made the occasion of a brilliant celebration in his native country. A monument to Scheele is to be unveiled in Stockholm.

THE Naturforschende Gesellschaft of Danzig are issuing invitations to the celebration of the 150th anniversary of their foundation on January 2 and 3, 1893. The meetings will take place on the Monday evening in the Friedrich-Wilhelm-Schutzenhaus, and on the Tuesday morning in the large hall of the Landeshaus, and the proceedings will wind up on the latter day with a dinner at 4 p.m. in the Schutzenhaus.

PROF. EDWARD PRINCE, of Glasgow, has been offered the important post of Commissioner and General Inspector of Fisheries for Canada by the Dominion Government, and has accepted the office. Prof. Prince is well known as an authority in Fishery Science. He holds the chair of Zoology in St. Mungo's College, Glasgow, and is President of the Anderson's College Scientific Society, and Vice-President of the Glasgow Natural History Society.

IT is announced that the King of Italy will open in person the International Medical Congress, which is to be held in Rome next year. An English committee is being formed to do what it can to secure the success of the Congress.

THE New York Academy of Sciences has organized a Biological Section, which is to hold monthly meetings. The opening meeting, at which Prof. H. F. Osborn presided, was held on October 17.

THE Victoria University has issued a list of University Extension lectures which are to be delivered in the course of the season 1892-93. They are to be given at many different centres, and include a wide range of subjects, among which various departments of physical and natural science hold a prominent place.

LIVERPOOL has sustained a real loss by the death of Mr. T. J. Moore, the late curator of the Liverpool Derby Museum. Mr. Moore had a wide knowledge of various branches of science, and did much to foster popular interest in the results of scientific inquiry. He died on October 31.

DURING the latter part of last week the weather continued very unsettled, the depressions which advanced from the Atlantic causing strong southerly winds or gales in many places, with frequent and heavy rain, while the temperature was uniformly high for the time of year, the daily maxima reaching nearly 60° in the southern parts, and exceeding 50° in the northern parts of the kingdom. On Saturday night a considerable decrease of temperature occurred, owing to the advance of an anti cyclone which subsequently spread over most of the country, the southerly winds gradually disappeared, and were succeeded by calm and variable airs. In the early part of the present week fog became prevalent in many parts of England, but the weather was generally fair with frosts over the inland districts. On Tuesday, however, fresh depressions were passing along our north-west coasts, and rain squalls became general over Ireland and Scotland, while southerly winds again became prevalent. The *Weekly Weather Report*, issued on the 5th instant, showed that the rainfall greatly exceeded the mean in the east and south of England, while in Scotland and the northern parts of England the fall was below the average. Since the beginning of the year, the eastern, Midland, and north-west districts of England have had three inches of rainfall in excess of the normal amount, while in the south-west of England there is a deficiency of 7.6 inches.

THE U. S. Hydrographic Office has issued a chart showing the submarine cables of the world, with their principal land connections. The chart is described by *Goldthwaite's Geographical Magazine* as a necessity to foreign commerce. It contains tables for the computation of rates to any part of the world.

THE November number of the *New Bulletin* contains sections on coffee cultivation in British Honduras, the prune industry of California, sugar cane borers in the West Indies, sisal hemp in Yucatan, Liberian coffee in the Malay native states, and Bombay aloe fibre. There are also miscellaneous notes, from one of which botanists will be glad to learn that after many unsuccessful attempts to introduce living examples of the interesting plant, *Dischidia rafflesiana*, Kew has at last succeeded, thanks mainly to the generosity of Dr. Treub, the distinguished director of the Botanic Gardens, Java, who sent a plant of it in a Warden case two years ago. This plant is now established and growing freely, producing numerous large pitcher-like leaves as well as the small normal hoyia like foliage. The morphological meaning of these pitchers has not yet been thoroughly worked out. "The species of *dischidia* all want a careful study. They cannot be described satisfactorily from dried specimens. The leaves change in form, and it is not ascertained in respect of many species whether they may or may not be converted into pitchers (ascidia)." (Hooker in "Flora of British India.") The plant at Kew is now under the special observation of Dr. Scott, hon. keeper of the Jodrell Laboratory. *D. bengalensis* is an old garden plant. It is cultivated at Kew in the Palm House. *D. rafflesiana* is for the present kept in one of the propagating pits.

AT the opening meeting of the twelfth session of the Junior Engineering Society on November 4, an excellent address was delivered by the president, Dr. John Hopkinson, F.R.S., on the cost of electric supply. His general conclusion on the subject is that to be ready to supply a customer with electricity at any moment he wants it, will cost those giving the supply not much less than £11 per annum for every kilowatt, that is for every unit per hour, and afterwards to give the supply will not cost very much more than 1d per unit. The clear apprehension of this point Dr. Hopkinson believes to be essential to the commercial success of electric supply. It is hopeless, he thinks, for electricity to compete with gas in this country all along the line, if price is the only consideration. But with selected customers, electricity is cheaper than gas. Surely, he adds, it is the inte-

rest of those who supply electricity to secure such customers by charging them a rate having some sort of relation to the cost of supplying them.

AN address delivered by Prof. Virchow at the opening of the recent International Congress of Archaeology at Moscow is printed in the current number of the *Revue Scientifique*. Prof. Virchow repeats in this address what he has often said before—that no trace of "the missing link" between man and the lower animals has been discovered either in the human skulls which are believed to be most ancient or in the physical organization of modern savages. He urges that the immediate task for anthropologists is to explain the origin of the existing human races, and to determine the causes by which these races, while retaining the power of hereditary transmission, have acquired their distinctive characteristics. At first sight, he says, it is easy to suppose that a dolichocephalic skull may be transformed into one of brachycephalic form, but it has not yet been shown that any dolichocephalic race has been actually transformed into a brachycephalic one, or *vice versa*. Prehistoric anthropology ought, he thinks, to find methods which would facilitate the recognition of the types of ancient races and peoples, and enable us to find them again among the races and peoples of the present day. It ought also, as occasion offers, to collect data with regard to those strange individual cases about which theories, as Dr. Virchow holds, have been prematurely formed, and which should be kept in "the scientific baggage" until we have secured intermediate links which will render it possible for us to unite them in a series.

ACCORDING to an official report of Captain von François, the dromedaries which have been introduced into the German territories in South-west Africa in connection with the parcel post service have more than fulfilled the expectations that had been formed about them. The climate suits them, and they are not affected by any of the prevalent cattle diseases. On the road between Lehmütang and Geinab they were six days without water, and on the seventh day, at Geinab, they did not seem to be very thirsty. In stony regions their feet do not, like those of unshod horses or oxen, suffer any injury. When loaded with a weight of 250 pounds, a dromedary advances at much the same rate as an ox-waggon. The only drawback connected with these useful creatures is that they are rather costly.

MR. A. E. DOUGLASS, first assistant at the Boyden station of the Harvard College Observatory, Arequipa, contributes an interesting paper to *Science*, October 21, on indications of a rainy period in Southern Peru. There is evidence to show, he thinks, that for many thousands of years, going back far beyond the recognized period of human habitation, the climate of Peru has been very much as it is at present. That was preceded by a slow rise of the land out of the sea, which caused the climate to change from wet to dry. But under the wet climate the elevation of the land was still too great, and perhaps the duration of the epoch was too short, to produce a luxuriant tropical vegetation, otherwise there would be to-day extensive coal-fields. The wet climate, however, was sufficient greatly to alter the face of the country. Lake Titicaca was of enormous area, fed perhaps by the melting glaciers. In the almost continuous rainy season, huge turbid rivers roared and tumbled down these western slopes of the Cordillera, while on each mountain summit vast quantities of snow fell, only to pursue its way down the steep slopes, carving out valleys, building up ridges, and by its melting wearing out deep ravines, which grow smaller as they become lost in the broad level plain below. Under such luxuriance of moisture the valley of Arequipa must have teemed with animal and vegetable life, the barren hills to the south were clothed in green, and the desert of La Joya blossomed like a garden.

A CAPITAL annotated catalogue of the mammals collected by Dr W L Abbott in the Kilima-Njaro region, East Africa, has been prepared by Mr F W True, and printed in the Proceedings of the fifteenth volume of the U S. National Museum, with several plates. Dr Abbott has presented to the National Museum many African collections, but none of them, according to Mr True, is of more interest than the collection of mammals. The specimens have been prepared with much care, the skins being almost invariably accompanied by the skulls and furnished with labels giving the locality and date of capture, sex, and other data. In determining the species Mr True has found it necessary to depend almost exclusively on the literature, on account of the lack of specimens for comparison, but the identifications have been made with much care, and may, he thinks, on the whole, be relied upon. Several species apparently new are represented in the collection *Dendrohyrax validus*, *Mus aquilus*, *Dendromys nigrescens*, *Sciurus undulatus*, *Cephalophus spadix*. On one who has studied the North American mammalian fauna in detail, Mr True says, the thought impresses itself that the condition of species, as regards variation, is different in the Ethiopian and Nearctic regions. In North America individual variation seems far less extensive than in Africa, while geographical variation appears to be more extensive and constant. In Dr Abbott's collection great individual variation is especially apparent in the genera *Galago*, *Genetta*, and *Canis*. It is true that the species of the last named genus everywhere present much individual variation, but in North America its chief variations appear to be geographical in character. The known range of several species is considerably extended by Dr Abbott's labours.

AN important contribution to spectroscopy appears in No. 10 of Wiedemann's *Annalen* in the shape of a paper on the infra-red emission spectrum of the alkali metals, by Benjamin W. Snow. The method is distinguished by the adoption of a modified form of the bolometer and a very delicate galvanometer with quartz fibre suspension. The fibre, supplied by Prof. Boys, was 40 cm long. With a scale at a distance of 3 m, a deflection of 1 mm corresponded to a current of  $1.5 \times 10^{-11}$  amp. The spectra were obtained by means of a silicate flint prism, so as to avoid the overlapping of the infra-red spectra which seems to be inevitable where gratings are used. Since no infra-red lines could be traced in the spectrum produced in the Bunsen or the oxy-hydrogen flame, the electric arc was used, the current being derived from the very uniform Berlin Central supply. The best arrangement for the arc was found to be a hole bored through the centre of the carbon, containing a "wick" of the compressed salt. The bolometer consisted of two platinum-thread resistances. A platinum wire embedded in silver was hammered flat, so as to have a breadth of 0.05 mm and a thickness of 0.00036 mm. Two such threads were fastened side by side with shellac on a mica frame. One of them was blackened in a turpentine flame and exposed to the light, the other being covered. The difference of resistance produced by the incident rays was measured by a Wheatstone bridge arrangement, with a shunt contrivance for enlarging the scale of the bridge wire. The resistance of each of the platinum ribbons under ordinary conditions was 75 ohms. The other branches of the bridge were made of German silver wire. The slit of the spectrometer was adjusted to 0.1 mm, corresponding to an angle of 1.68 minutes of arc in the spectrum, whilst the breadth of the platinum thread corresponded to an arc of 1'.6. The current through the bridge was maintained at one-fortieth ampere. In the measurement of the intensity of the lines, the energy of radiation was taken as proportional to the first throw. It was found that a standard candle at 1 m. distance gave a throw of 150 mm. A preliminary investigation of the carbon spectrum revealed a large number of

bands reaching up to  $\lambda$  20620, the principal less refrangible bands being between

7000 and 7700  
7850 and 8600  
9000 and 10000  
10750 and 11600  
13700 and 15000

These were made up of innumerable fine lines. It was also observed that the carbon spectrum vanished in comparison with the metallic spectrum as soon as the latter was brought into play. Of the five metals investigated, viz., sodium, potassium, rubidium, lithium, and cesium, the two rarest were found to be specially rich in infra-red lines. Sodium showed maxima at 8187, 11270, 12400, and 18360, potassium at 7670, 10820, 11580, 12250, and 14610, lithium at 8070, rubidium at 7910, 9980, 13120, and 14760, and cesium at 8380, a large one at 8820, and others at 9980, 13270, and 14530. Kayser and Runge's empirical law for the alkalis was confirmed for the infra-red of lithium and sodium, but not for the other three metals.

MR ELLIOTT COUES, of the Smithsonian Institution, defends, in *Science* the rule, in biological nomenclature, "once a synonym, always a synonym," for the form of which he believes himself to be in some degree responsible. He illustrates the real meaning of the aphorism in the following way. Let there be a genus *Smithia* in botany. Let a genus *Jonesia* then be named. Let *Jonesia* then be found to be the same genus as *Smithia*. Then the name *Jonesia* "lapses into synonymy," and cannot be thereafter applied to any other genus in botany. That is all that is meant by the saying "once a synonym, always a synonym." In other words, if *Jonesia* is not good for what it originally meant, it is good for nothing, it is to be deleted absolutely, and cannot come into re-existence by transfer to any other genus. Mr Coues shows that the same principle holds for all specific names within their respective genera. Example. Let there be a *Rosa Smithi*. Let some one then name a *Rosa Jonesi*. Let *R. Jonesi* be considered to be the same species as *R. Smithi*. Then there can never be a *R. Jonesi*, that is to say, no other species of *Rosa* can be specified as *Jonesi*. But, of course, if any one discovers, after this reduction of *Jonesi* to a synonym of *Smithi*, that what had been called *R. Jonesi* is a good species, then *Jonesi* revives as the name of that species, and the fact that it had been (erroneously) regarded as a synonym of *Smithi* is no bar to its use in its original sense.

THE Geological Survey of America has published a paper, by Mr J S Diller, on the Geology of the Taylorville region in the Sierra Nevada, California, immediately north of the fortieth parallel. In this region there are eighteen sedimentary formations and seventeen eruptive masses. The former have a total thickness of 24,500 feet, 17,500 feet are probably Palaeozoic, and 7000 feet are Mesozoic. Among the sedimentary rocks, one horizon in the Silurian, two in the Carboniferous, three or more in the Trias, and five in the Jura have been definitely recognized by fossils. Among the eruptives there is great variety. Their extravasation, beginning early in the Palaeozoic, recurred vigorously in the Triassic and at the close of the Jurassic, and, finally, also in the Neocene and Pleistocene. The dioritic rocks of the region are a portion of the great granitic mass of the upper Sierra Nevada, and are evidently eruptive, with well-defined contact phenomena in Triassic formations. Their eruption is certainly post-Triassic, and may have taken place immediately at its close or after the deposition of the Jurassic. There are at least four unconformities in the geologic column of the Taylorville region. During the greater part, if not the whole, of the Palaeozoic, the sea covered the region now occupied by the northern portion of the Sierra Nevada. The great disturbance at the close of the Carboniferous may

have been accompanied by an uplift, forming land during the early Triassic, but if so, it subsided and was ready to receive the deposits of the upper Triassic. The disturbance at the close of the Triassic formed no land in the northern Sierra region, but that which closed the Jurassic was accompanied by a great upheaval, excluding the sea to the western base of the Sierras. The general structure of the Tylorville region involves a synclinal and two limiting anticlinals. After the folds were overturned toward the north-east, the Grizzly anticlinal was affected by an overthrust fault in the same direction. The throw along this fault in the older strata is so much greater than in those of Jurassic age as to suggest that a large part of the displacement took place at the close of the Triassic, and was followed by movement on the same plane at the close of the Jurassic.

MR. STANFORD has issued an interesting and valuable contoured map of the county of London. The scale is three inches to a mile. The contour lines or lines of equal altitude are drawn at 25 feet intervals. The lowest contour is 25 feet above the level of the sea, ordnance datum, which is 12 feet 6 inches below Trinity high water. The whole of the alluvial flat lying below the lowest contour, or at a less altitude than 12 feet 6 inches above the river Thames (Trinity high water mark), is covered by a dark brown tint.

THE third volume of reports upon the fauna of Liverpool Bay and the neighbouring seas has been issued. The reports have been written by members of the Liverpool Marine Biology committee and other naturalists, and edited by Prof. W. A. Herdman, F.R.S.

MESSEURS GURNEY AND JACKSON have published the *Zoological Record* for 1891. It is the twenty-eighth volume of the series. Mr. D. Sharp, F.R.S., has acted as editor, and has had the co-operation of many able zoologists. It is intended that in future the volume shall be published in August or September.

PHOTOGRAPHERS will read with great interest an admirable paper by Captain Abney, in the November number of the *Journal of the Camera Club*, on "shutters," which he describes as "a piece of apparatus which is the very joy and toy of the photographer's existence." The paper is fully illustrated.

THE Rev. L. A. Walker sends to the current number of the *Entomologist* some statistics of the entomology of the Hague, where he acted as chaplain during July. The entomology of Holland seemed to him very disappointing in number of species, and also in individuals in the great majority of cases, less productive, in fact, than the ordinary run of country places at home.

AT the meeting of the Linnean Society of New South Wales on September 28, Mr. R. Etheridge, junior, exhibited seeds of the "Bean-tree," possibly an *Erythrina*, from Macdonald ranges, Central Australia. The seeds are strung and used as necklaces by the aborigines, who use the wood of the same tree for producing fire by friction, and also for shields, on account of its lightness.

A COMPOUND of gold and cadmium of the composition AuCd has been isolated by Messrs. Heycock and Neville, and is described by them in the November number of the *Journal of the Chemical Society*. During the course of a series of experiments last year upon solutions of gold and cadmium in melted tin, it was observed that the amount of lowering of the freezing-point of the tin by the simultaneous introduction of gold and cadmium was considerably less than the sum of the effects which each of the two latter metals would produce alone. It was surmised that this difference must be due to combination between the gold and the cadmium. Moreover, the product of this combination appeared to be only sparingly soluble in tin,

for a considerable quantity of a crystalline precipitate was produced, but owing to the difficulty of freeing it from the tin which solidified over it upon removal, the compound was not obtained in a state of sufficient purity to enable a definite conclusion concerning its composition to be arrived at. Messrs. Heycock and Neville now announce that they have succeeded in preparing the compound in an entirely different manner, and in isolating it in a state of comparative purity. The following is the best mode of procedure.—A piece of the hardest combustion tubing is sealed at one end and slightly bent in the middle so as to form a V-tube of very large angle. A quantity of pure gold is placed in the sealed limb, together with three or four times its equivalent of cadmium. The open end is then drawn off so as to enable the tube to be exhausted by means of the Sprengel pump. As high a vacuum as possible should be obtained, and the tube subsequently sealed. The apparatus is then arranged upon a combustion furnace in such a manner that the excess of cadmium when liquefied may run away from the alloy. When the cadmium first melts it is advisable to vigorously shake the tube so as to diffuse the gold well among the cadmium. The combination then occurs suddenly, accompanied by bright incandescence of the gold. When the larger excess of cadmium has been allowed to run away from the compound, the end of the tube containing the latter is heated for about five hours to a temperature about that of the softening of glass, when the remainder of the excess of cadmium distils regularly off, until towards the expiration of the five hours no further condensation occurs. The product thus left behind was found in three successive experiments to contain about 63.7 per cent of gold, the percentage required for a compound of the composition AuCd. The compound of gold and cadmium thus obtained presents a silvery greyish white appearance, is very brittle, and exhibits a crystalline fracture. The action of acids upon it is somewhat singular. Cold acids appear to be without material action upon it, but hot nitric or hydrochloric acid attacks it with great energy, the cadmium passing into solution and the gold being left in the shape of the original ingot.

THE additions to the Zoological Society's Gardens during the past week include a Purple-faced Monkey (*Simnopithecus leucopymnus*) from Ceylon, presented by Mrs. Elgee, six Short-tailed Voles (*Arvicola agrestis*) from Scotland, presented by Mr. J. E. Harting, F.Z.S., two Laughing Kingfishers (*Dacelo gigantea*) from Australia, presented by Mr. J. W. Hornsby, a Golden Eagle (*Aquila chrysaetos*) from Labrador, presented by Mr. J. G. Baxter, a Jackdaw (*Corvus monedula*) British, presented by the Rev. H. W. Reynolds, three — Geckos (*Gekko verticillatus*) from Burmah, presented by Mr. W. G. Bligh; two American Darters (*Plotos anhuanga*), a Common Boa (*Boa constrictor*) from South America, four Bar-tailed Pheasants (*Phasianus versicolor* ♂ & ♀ ♀) from China, purchased.

### OUR ASTRONOMICAL COLUMN

A BRIGHT COMET is announced in Andromeda, seventy seconds preceding Struve 72.

COMET BARNARD (OCTOBER 12).—The following is a continuation of the ephemeris we gave last week of Comet Barnard taken from *Astronomische Nachrichten*, No. 3125.

Ephemeris for 12h. Berlin M.T.						
1892.	h.	m.	s.	Decl.	Log r	Log Δ
Nov 11	20	46	49	+2° 33' 3"		
12		49	40	2 15 7		
13		52	38	1 58 3	0.2262	0.1648
14		55	25	1 41 2		0.097
15	20	58	19	1 24 4		
16	21	1	14	1 7 9		
17	21	4	9	+0° 51' 6"	0.2250	0.1713

It may be mentioned that an *Astronomische Nachrichten* circular note contains rather a modified edition of the above places deduced from observations made on October 16, 20, and 25.

Thus for the 13th, the R A is given as 20h 54m 24s (app), and declination (app) + 1° 54' 5", and for the 17th, R A (app) 21h 6m 39s, and declination (app) + 0° 46' 4".

COMET BROOKS (AUGUST 28)—Owing to the rapid brightening of Comet Brooks, we give the following ephemeris continued from the same source as mentioned last week (*Astronomische Nachrichten*, No. 3125).

#### 12h Berlin M T

1892.	R A app h m s	Decl app ° ' "	Log r	Log Δ	Br

17	23 15	2 18 4			

OCCULTATION OF MARS AND JUPITER BY THE MOON.—Prof. Barnard communicates his observations of the occultation of Mars and Jupiter by the moon, which occurred in one week during last September, to the *Astronomical Journal*, No. 276. The instrument used was the 12 inch equatorial and the seeing was defined as being very fine on both occasions. At the disappearance of the former planet, which took place at the dark limb of the moon, nothing very striking was noticed, the moon's limb at that point being sharp and not dusky, as had been previously seen in an occultation of Jupiter. The times of disappearance and appearance (Mount Hamilton mean time) were—

	Disappearance h m s	Reappearance h m s
1st contact	9 9 35 8	10 45 56 0 (1s late?)
Half obscured	9 10 4	10 26 17
2nd contact	9 10 37 1	10 26 52 2

In the case of Jupiter, which disappeared at the bright limb, a narrow shadow band was noticed fringing the limb where the planet appeared to cut it. This is due, as Prof. Barnard thinks, to the effect of contrast. The times of contacts were as follows—

	Disappearance h m s	Reappearance h m s
1st contact	17 28 10 4	18 33 17 5 (2s late?)
Half obscured	17 28 55 0	18 33 50
2nd contact	17 29 45 7	18 34 33 7

MOTION OF THE SOLAR SYSTEM.—The question of the exact position of the point in the heavens to which the sun with his system is travelling has been the object of much research and computation, and the present co-ordinates are now considered as being about R A 267° and declination + 31°.

The determination under consideration (*Astronomical Journal*, No. 276) has been undertaken by Prof. J. G. Porter, and is based on the proper motions of 1340 stars, contained in the Publication of the Cincinnati Observatory, No. 12. The method employed for computing the co-ordinates of the apex of the sun's way is that of Prof. Schonfeld, the stars were grouped in four divisions, Division I including those whose yearly proper motion was less than 0" 30 and contained 576 stars; Division II, motion from 0" 30 to 0" 60, containing 533 stars; Division III, motion from 0" 60 to 1" 20, containing 142 stars; and lastly, Division IV, the motion exceeding 1" 20, 70 stars being included. From these four groups the following values have been deduced, where  $\sigma$  and  $\tau$  represent the co-ordinates of the apex of the sun's course and  $\rho$  the velocity of the sun's motion—

	$\sigma$	$\tau$	$\rho$
I	281°	+53 7	0 16
II	280°	+40 1	0 30
III	285°	+34 0	0 55
IV	277°	+34 9	0 66

The last determination of these co-ordinates was made, if we are not mistaken, by Prof. Stumpe, and were given in *Astronomische Nachrichten*, Nos. 2999–3000. The values there de-

duced agree very well with those in question, with the exception of  $\tau$  in Group I and  $\sigma$  in Group IV, which consequently throw the mean values rather out. Adopting the same notation, he obtained—

	$\sigma$	$\tau$	$\rho$
I Group	287 4	+42 0	0 140
II "	279 7	40 5	0 295
III "	287 9	32 1	0 608
IV "	285 2	30 4	2 057

Summing up the values obtained by some previous workers, the following table gives the co-ordinates obtained—

Name	R A	Decl	No of stars used in reduction
Gauss	259 2	+30 8	—
Argelander	259 9	32 5	390
O. Struve	261 5	37 6	392
Mädlar	261 6	39 9	2163
Airy	261 5	24 7	113
Dunkin	263 7	25 0	1167
Rancken	284 6	31 9	106
Birchoff	285 2	48 5	480
I. Struve	273 3	27 3	2509
Stumpe	285 1	36 2	1054
Porter	281 2	40 7	1340

### SOME REMINISCENCES OF THE MAORIS

MR W. COLENSO, F.R.S., has often been asked to record some of his reminiscences of the Maoris, whom he has for very many years had opportunities of studying. This he has now done in a paper printed in the Transactions of the New Zealand Institute (vol. xxiv), some extracts from which may be of interest for various classes of readers. He says—

*Of the Mako Shark*.—Fifty years ago (to go no further back) a Maori chief would be known by wearing certain emblems or insignia indicative of rank, one of which was the tooth of the mako as an ear pendant; and, as such were plentiful, though distributed, the thought often occurred to me in my early travelling days, 'What a number of the fish mako there must have been captured or obtained by the Maoris to yield such a large number of teeth!' Moreover, on inquiry I invariably found that all the teeth I saw were prized heirlooms, and had descended to the present possessor through several generations, and (as far as I could learn) none had been recently acquired. And while, when travelling along the sea coasts for many a league on both sides of the North Island during several years, and always on foot, I had both seen and heard of a number of large sea animals (fishes and mammals) that were driven on shore on the sandy beaches in severe gales from the sea, I never knew of a single mako shark, nor had the Maoris resident on those shores ever heard of one being cast up.

In replying to my numerous inquiries by letter respecting the mako, made many years ago, an intelligent aged Maori chief living on the east coast wrote as follows (or, rather, he being of the old school, and unable himself to write, a young adherent did so at his dictation). I give a literal translation of portions of his letter—

"You ask, did I ever see a mako fish? Yes; and it is a very large creature, the biggest of all the sharks (*mango*)—in length 2 fathoms measured (*erua mao whanganga nei*), and in thickness 1 foot. It is a true shark, but called by us a mako on account of its teeth. You also inquire concerning its fat or oil, and the edible qualities of its flesh, whether considered choice by us Maoris. Now, there are many kinds of shark, as the mako, the *karaerae*, the *puke*, the *ururoa*, the *matini*, the *tahaponnamu*, the *tasari*, the *tsatere*, and the *mangotara*, and I have not eaten of them all, and therefore I do not know how nice or how fat they all are; and so of this one, the mako. But, my friend, this fish was never desired as an article of food—never so used by us Maoris. The only part of it that we sought and greatly desired to have was its head, and this solely on account of its teeth. When caught out at the deep-sea fishing-grounds its body was never hauled into the canoe, but the head was cut off while it was still in the sea and alongside of the canoe (*ka tapahia moemaha te upoko*); this done, and the head secured, the body was left to drift away on the sea. The head was also immediately wrapped up securely in a cloth—mat (*kaahu*), lest it should be noisily wondered at by those who

were strangers or unacquainted with it (*ko umereta e nga tangata tauhou*). You also ask what instrument was used for cutting off the head of the *mako*. What, indeed? Why, the saw made of the teeth of the *tatere* shark firmly fixed on to a wooden blade (*he naho tatere, he mea hohou ki runga ki te rakaui*). You further inquire respecting the number of its teeth. There are eight—that is, large ones from within—and also eight smaller ones of them outside. Besides those there were several much smaller ones in front or outside (*o waho rawa*), but these I never counted, and therefore cannot give their exact number."

He also wrote (in another and subsequent letter) in answer to my further inquiries: "There are four very large teeth from the beginning, or within. These are called *ira*, and are kept for ear-pendants. Altogether there are eight teeth—that is, four very large ones, and four smaller, making eight in all. The outside teeth resemble those of the *tatere* shark, and are only termed teeth (*nika*), these have no other name, but those that are kept for ear-pendants are called *au iei*. Then, you wish to know how the *mako* was captured by us Maoris in the olden times. Listen. This fish was never taken as other sharks (*mango*) were, with hook and bait, none of our fish hooks would be strong enough to hold it, they would soon be broken. Now, when the fishing-canoe was out fishing, and had been a long time there catching fishes of various kinds, suddenly a *mako* would be seen coming leisurely along on the surface of the water (*e hara mai noa ana i te kire o te wai, ara i te kare o te wai*). Then the man who saw it would shout out to his companions in the canoe, 'Haul up our land' (*Hutia mai to tauu whenua*), not naming the fish, and when the *mako* was pretty near to the canoe, about three yards off, then the big tempting bait was let low down before it, and on the *mako* seeing the bait it would bend down its head to seize it (*ka tupou te upoko*), when its tail would be upraised above water. Then a noosed rope would be flung over its tail (lasso-fashion) and quickly hauled tight, which would secure the tail within the noose hard and fast. And away would speed the canoe at a fleet rate towards all sides of the sea and sky, being continually turned about in all directions by the fish, the man who had noosed it always holding on to the rope. At last, being exhausted, the *mako* died, then it floated, when its head would be cut off, as I said before. This was our common manner of catching the *mako* fish (*kotona his tonu teue o tenesika o te mako*), often also called by us a monster (*tanuwha*), and hence arose the term of monster-binding (*heretaniwha*), owing to it being securely noosed and bound with a rope flung over its tail." Here ends the interesting narration of my worthy old Maori correspondent, who died soon after.

I have never seen a *mako* fish, and I am in doubt whether it is yet fully known to science. It is evidently one of the deep-water fishes. The first mention of it by skilled scientific observers that I have noticed is in Sir James Ross's "Voyage to the South Seas," wherein it is stated that on nearing the Chatham Islands, in November, 1841 (within a week after leaving their winter quarters and anchorage in the Bay of Islands), "the long snouted porpoises were particularly numerous." One of these creatures was struck with a harpoon, and in its formidable jaws we found the teeth which the New-Zealanders value highly as ornaments, and which had puzzled us greatly to ascertain to what animal they belonged" (vol. ii, p. 134). Those Antarctic Expedition ships had spent several months in the Bay of Islands, and the officers had frequent opportunities of seeing and examining the teeth of the *mako*, and very likely had purchased some from the Maoris, as they were diligent in acquiring natural specimens, and curios and ornaments of all kinds.

Professor Hutton, in his "Catalogue of the Fishes of New Zealand" (published by the Government in 1872), considered the *mako* to be the "*Lamna glauca* = tiger-shark," but he says, "The shark from which the Maoris obtain the teeth with which they decorate their ears is probably this species, but I have seen teeth only" (i.e., p. 77).

Subsequently Professor Julius von Haast (in 1874) read a paper before the Philosophical Institute of Canterbury (Trans. N.Z. Inst., vol. vii., p. 237) on the *mako* of the Maoris, which, he says, is *Lamna cornubica*, the porbeagle shark, and not *L. glauca* as had been supposed by Professor Hutton. But Professor von Haast had only a small young specimen (or, rather, its skin) to examine, which two North Island Maoris, then engaged at Christchurch Museum, pronounced to belong to

a young *mako*, and informed him that this fish in its adult state was about 12 ft long. The animal to which the skin belonged was 4 ft 10 in long. Professor von Haast also gives much information relative to the teeth of his small specimen (differing widely from my Maori friend's description given above), their number, form, and size, the colour of its skin, &c. Still, as I take it, there are reasonable doubts as to that specimen being a true *mako*, I think it is highly probable that his two Maori informants had never seen a real *mako* shark.

Couch, in his celebrated work on "British Fishes," in his account of the porbeagle shark, gives a drawing of it from nature, and also others of its teeth and jaws, which appear to be different from those of the *mako*, being much more slender, and semi-terete, undulate, and sharply pointed (vol. i, pp. 41-44).

My object in writing this notice of the *mako* shark is mainly to relate the ancient Maori mode of capturing it.

*Of the Preparation of Black Pigment for Tattooing*.—The ancient Maoris had more ways than one of obtaining the black substance used in tattooing, which colouring matter also varied in quality, partly owing to what it was made from, that for the countenance being superior to that used for the lower parts of the body. One way of obtaining the best kind was as follows:—

First, two proper careful men were selected for the work. This, too, was done with ceremony, they being (for the time) *tapu* (i.e., under the laws of *taboo*)—rigidly set apart. A small kiln-like furnace (*ruangarehu*) was excavated in the side of a hill suitably situated. The substances to be used in burning for their soot—*kauri-resin* (*kapa*) and the resinous veins of white pine wood (*lapara*)—were got ready, a net made from the *whararangi* flax leaves finely split, composed of very small and close meshes, and beaten well, so as to be rough and scabrous from long broken fibres, in order the better to catch and retain the soot (*awe*), which was intended to adhere only to the network. This net was fixed properly and securely over the top opening or chimney of the kiln, and above it were placed thick mats and such like, to prevent the escape of the burning soot and smoke. All being ready, a very calm fine night was chosen for the firing of the kiln—a night in which there should not be the least breath of moving air, and, the kiln being fired, those two men remained all night at their post, attending to their work, carefully feeding the fire. When all the resinous substances were burnt up, and the kiln cold—the calm weather still continuing—the soot was carefully collected and mixed up with the fat of birds, and then given to a Maori dog to eat, which dog had also been early set apart for this work—tied up, made to fast, and kept hungry, that it might perform its part and eat the prepared morsels with avidity. After devouring the mixed food the dog was still kept tied up, and not allowed to eat any other aliment until it had voided the former. When the faeces were evacuated they were carefully gathered, and mixed up and kneaded with bird's oil and a little water, and, when this mixture became dry and hard, it was put up securely into a large shell, or into a hollowed pumice or soft stone, and laid by carefully, buried in the earth, for future use. It is said to have possessed no disagreeable odour when dry (though it had while fresh), and, though long kept, it did not become bad nor spoil through keeping, which, on the contrary, was said to improve it, and it was very much prized.

It was this pigment, so put up and kept, that was the origin of one of their proverbs, "*Puritia to ngarahu kauri*" = Keep to thyself thy *kauni-resin-soot* pigment. This saying was used when a person was unwilling to give what was asked, the same being some common thing, and not at all needed by the avacious owner. But there is a double meaning here in this simple sentence (proverb)—namely, "You may never require it, or live to use it" (See Trans. N.Z. Inst., vol. xii., p. 145.)

*Of the Manufacture of their Long Spears*.—Some of their spears were very long. Of these there were two kinds. One kind was made of hardwood, *rimu* (*Dacrydium cupressinum*). This was used in defending their forts and stockades before the introduction of firearms, being thrust through the palisades at close quarters against the legs and bodies of the invaders. The other kind was much lighter, though longer, being made of the light wood of the *tawa-tree* (*Banksia medialis tawa*), and used only for the spearing of pigeons when they were sitting on the top of a high tree. This spear was tipped with a flatish serrated bone 3 inches—5 inches long, usually coarsely barbed on one lateral edge, and sharply pointed; the bone being human, and a portion of that of the arm or leg, and, of course, of their

deadly enemies. Seeing that these long spears were always made from heartwood of their tallest trees, it was a mystery to me how they managed to manufacture them, the hardwood ones being from 16 feet to 20 feet and the others from 20 feet to 35 feet long, and it was not until my first visit to the Urewera Tribe, at Ruatuhuna, in the interior beyond Waikare Moana, in 1841, that I discovered how it was effected. This patient performance has ever seemed to me a notable example of one of their many laborious and persevering works. For it must never be forgotten, in considering their ancient laborious and heavy works, especially in hard substances, as wood, bone, and stone, that they accomplished all without the use or knowledge of iron or any other metal.

First, a straight, tall, and sound *tawa*-tree was selected in the forest. This was felled with their stone axes. Its head and branches having been lopped off, it was dragged out into the open ground, and split down the middle into two halves. If it split easily and straight, then it would probably serve for two spears, if each half turned out well in the working. The next thing was to prepare a long raised bed of hard tramped and beaten clay, 35 ft. 40 ft. long—longer than the intended spear—the surface to be made quite regular and smooth (like a good asphalted kerb town walk of the present day). On to this clay bed the half of the *tawa* tree was dragged, and carefully adzed down by degrees, and at various times, to the required size and thickness of the spear. It was not constantly worked, but it was continually being turned and fixed by pegs in the ground, to keep it lest it should warp and so become crooked. It took a considerable time—about two years—to finish a spear. The last operation was that of scraping with a broken shell or fragment of obsidian, and rubbing smooth with pumice-stone. When quite finished and ready for use a suitable tall and straight tree was found in, or on the edge of, the forest, its trunk was trimmed of branchlets, &c., the long spear was loosely fixed vertically to it, so as to run easily through small round horizontal loops girt to the tree, and placed at some distance from each other, the tip of the spear concealed, yet protruding near the topmost branches of the tree, and, as the pigeon is a very thifty bird (especially, I should think, after feeding on the large fruits of the *tawa* and of the *miru*—*Podocarpus ferruginea*—trees, which are hot and piquant), the Maoris made small corrugated vessels of the green bark of the *totara* tree that would hold water, and fixed such on the top of the tree to which the long spear had been lashed, and by-and-by, when the bird was settled above after drinking (for it is a very quiet bird, sitting long after feeding), the spear was gently pulled down by its owner below on the ground, and sent up with a jerk into the body of the pigeon. I have seen the fixed spear thus used in the forests, and have eaten the bird so captured.

I may here mention that I have also seen those totara-bark dishes, with water in them, fixed high up on the big branches of trees in the woods in the Urewera country, having flax nooses so set over the water as to catch and hold fast the pigeon in its drinking. I have seen pigeons so caught, the Maoris climbing the trees naked with the agility of monkeys to secure their prizes.

From the large amount of labour and the time consumed in the making of a long spear, and its great beneficial use when made, arose a good proverb among them relative to industry in tillage, &c., and to being prepared—"Kahore he taranga tahare i te ara"—You cannot hew a bird-spear by the way. Meaning Without timely preparation you may die from want of food, though the pigeons are plentiful in the forests near you.

Of the Fine Smelling-sense and Taste of the Ancient Maoris for Perfumes—I have already more than once, and in former papers read here before the Institute, touched on the superior powers of sight of the ancient Maoris,<sup>1</sup> and it has often occurred to my mind that they also possessed a very keenly developed sense of smell, which was largely and quickly shown whenever anything sweetly odiferous, however fine and subtle, had been used—as eau de Cologne, essence of lavender, &c. Indeed, this sense was the more clearly exhibited in the use of their own native perfumes, all highly odorous and collected with labour. Yet this sensitive organization always appeared to be the more strange when the horribly stinking smells of two of their common articles of food—often, in the olden times, in daily use—were considered: rotten corn (maize, dry and hard, the cob) long steeped in water to soften it, and dried shark. The former,

however, has long been abandoned, yet at one period every village at the North had its steeping-pit.

In a paper I read here at our June meeting I mentioned some of the very small Hepaticæ (*Lophocolea* and *Chiloscyphus* species) as being used for perfume by the Maoris, who called them *piripiri*. Their scent was pleasant, powerful, and lasting. Hooker, in describing those plants, has mentioned it from dried and old specimens. Of one species, *Lophocolea pallida*, he says, "odour sweet," of another, *L. novaezealandiae*, "often fragrant," of another, *L. albidodonta*, "odour strong, aromatic," of another, *Chiloscyphus fissistipus*, "a handsome strongly-scented species," and he has further preserved it to one of them in its specific name, *C. piperitius*, "odour of black pepper."

There were also two or three ferns—viz., *Hymenophyllum sanguinolentum*, a very strong smelling species, hence too its specific name, dried specimens not only retain their powerful odour, but impart it to the drying papers. *Polypodium pustulatum*, having an agreeable delicate scent and *Doodia fragrans*, a neat little species, this last was so far esteemed as sometimes to give name to the locality where it grew, as *Puke mokimoki*,<sup>1</sup> the little isolated hill which once stood where the Recreation ground now is in Napier, that hill having been levelled to fill in the deep middle swamp in Monroe Street.

One of the *Pittosporum* trees, *tawhiri* (*P. tenuifolium*), also yielded a fragrant gum, but the choicest and the rarest was obtained from the peculiar plant *taramea* (*Aciphylla colensoi*), which inhabits the alpine zone, and which I have only met with near the summits of the Ruahine Mountain-range, where it is very common and very troublesome to the traveller that way. The gum of this plant was only collected through much labour, toil, and difficulty, accompanied, too, with certain ceremonial (*taboo*) observances. An old *tohunga* (skilled man, and priest) once informed me that the *taramea* gum could only be got by very young women—virgins, and by them only after certain prayers, charms, &c., duly said by the *tohunga*.

There is a sweet little nursery song of endearment, expressive of much love, containing the names of all four of their perfumes, which I have not unfrequently heard affectionately and soothingly sung by a Maori mother to her child while nursing and fondling it—

Iaku hei piripiri,  
Iaku hei mokimoki,  
Iaku hei tawhiri,  
Iaku kē i taramea.

My little neck-satchel of sweet-scented moss,  
My little neck-satchel of fragrant fern,  
My little neck-satchel of odiferous gum  
My sweet smelling neck-socket of sharp-pointed *taramea*.<sup>2</sup>

Here I may observe that to the last one of the four the word *kati* is prefixed: this word—meaning, to sting, to bite, to puncture, to wound sharply and painfully—is added to indicate the excessive sharpness of the numerous leaves and leaflets of the *taramea* plant (hence judiciously generically named by its early discoverer, Forster, *Aciphylla*=needle pointed leaf), and the consequent pains, with loss of blood, attending the collecting of its prized gum, thus enhancing its value.

This natural and agreeable little stanza, one of the olden time, has proved so generally taking to the Maori people that it has passed into a proverbial saying, and is often used, hummed, to express delight and satisfaction—pleasurable feelings. And sometimes, when it has been so quietly and privately sung in a low voice, I have known a whole company of grey-headed Maoris, men and women, to join in the singing to me, such was always indicative of an affectionate and simple heart. How true it is, "One touch of nature makes the whole world kin!"<sup>3</sup>

In the summer season the sleeping-houses of their chiefs were often strewn with the large sweet-scented flowering grass *karehu* (*Hierochloa redolens*). Its odour when fresh, confined in a small house, was always to me too powerful.<sup>4</sup>

<sup>1</sup> Mokimoki Hill, from *mokimoki*, the name of that fern.

<sup>2</sup> See Trans. N. Z. Inst., vol. xii., p. 148.

<sup>3</sup> It is pleasing to notice that the observant artist Parkinson (who was with Sir Joseph Banks as his botanical draughtsman, and Cook on his first voyage to New Zealand) makes special mention of those little satchels in his Journal, saying of these Maoris who came off to ship in their canoes, "The principals among them had their hair tied up on the crown of their heads with some feathers, and a little bundle of perfume hung about their necks." (Journal, p. 93). Captain Cook, also, has similar remarks respecting the young women.

<sup>4</sup> Sir J. D. Hooker thus writes of this fine, sweet-smelling grass in his "Flora Novae Zealandiae": "A large and handsome grass conspicuous for its delicious odour, like that of the common velvet grass (*Anthranthum*) of England, that gives the sweet scent to new-made hay." (J. D. C., vol. ii., p. 300). A closely-allied northern species (*H. bernalis*), which was also supposed to

Here, in conclusion, I may briefly mention an instance of their correct discrimination on the contrary side, clearly showing how well and closely the ancient New-Zealanders agreed in his opinion of a plant with the highly civilized scientific visitor already named above, the botanist Forster. Forster named the *Coprosma* genus from the fetid odour of the first species he discovered in the South Island, which signification he also continued in its specific name, *C. fetidissima*. This shrub also bears a similar Maori name, *hupiro*, highly expressive of its very disagreeable smell.

*Of their Textile Manufactures*—These were formerly prominent among the great industrial achievements of the Maoris, and always elicited the admiration of their wondering visitors.

I divide them into two great classes—(1) of garments, which were woven; and (2) of threads, cords, lines, and ropes, which were spun.

Nature had given to the Maoris one of her choicest gifts in the well known flax plant (*Phormium*), of which there are two ascertained and valid species (*P. tenax* and *P. colensoi*), and several varieties. These plants are pretty general throughout New Zealand, and are well known to the Maoris by the common names of *harakeke*, *wharanui*, *whakariki*, and *ishore*—excluding those of the many varieties as known to them.<sup>1</sup> So that what they may have lost on the one hand through not having the valuable wild edible fruits of other South Sea Islands (as the cocoanut, bread fruit, plantain, &c.) they more than merely gained in their flax plant, which is also common, and almost endemic, being only found outside New Zealand in Norfolk Island.

And here I may briefly mention an anecdote of the flax plant. On my arrival in this country the Maoris (who knew nothing, or very little, of any other land) would often inquire after the vegetable productions of England, and nothing astonished them more than to be told there was no *harakeke* growing there. On more than one occasion I have heard chiefs say, "How is it possible to live there without it?" also, "I would not dwell in such a land as that." This serves to show how highly they valued it. Moreover, at first and for many years the principal export from New Zealand prepared by the Maoris was the fibre of this plant—all, too, scraped with a broken shell, leaf by leaf.

1. *Of their Woven Articles (or Garments)*—I do not intend to say much of them in this paper. Many of them are well known, and still to be found in use among the Maoris, but their manufacture has for many years sadly deteriorated. Indeed, I have not seen a newly-made first quality clothing mat for the last twenty to thirty years, and I very much doubt if such can now be made at all. Not that the art of weaving them has been entirely lost, but the requisite taste, skill, and patience in seeking and carefully preparing and using the several parts (including their dyes) are no longer to be found among the Maoris. I sometimes indulge in a contemplating reminiscence—an idea—a pleasing reverie of the long past—of great gatherings of Maoris, tribes and chiefs, and at such times the figures of some head men I have known, clothed in their handsome, clean, and lustrous dress-mats (*kaitaka* and *aronui*), would stand forth in pleasing high relief. The close and regular weaving of such flax dresses, having their silky threads carefully selected as to fineness and uniformity of colour, and their smooth, almost satiny appearance, as if ironed or calendered when worn new, was to me a matter of great satisfaction—a thing to be remembered—"a joy for ever."

Those best dress-mats were always highly prized, both by Maoris and Europeans, and brought a high price. I well recollect a young lady, daughter of very respectable early English settlers in the Bay of Islands, who, when she came across the inner harbour in a boat with her parents to attend the English Church service on Sunday mornings in the Mission chapel at Paihia, often wore one of them folded as a shawl, and to me it seemed a neat and graceful article of dress.

Three things more in connection with these fine mats I will not relate. One, the cross-threads in weaving were always of a

different sort of flax—the wett and the woof of these mats were not both taken from the same kind of flax, the second, that extremely soft lustrous appearance was given to the flax fibres by repeated tawing done at different times—it was a pretty sight to see the various skeins of flax fibres in their several stages of preparation neatly hung up in the weaving shed, the third, that in the weaving of one of these garments, if a thread showed itself of a different shade of colour, that part of the garment was carefully unravelled to take it out, and to substitute another better suited in its stead. It was also from this superior knowledge and close attention to their work that the principal chiefs frequently took women who were clever at making those things to be their wives, in order to secure to themselves their valued manufactures.

They also wove very good and useful floor and bed-mats of unscraped flax-leaves, split into narrow lengths and carefully bleached in the sun—these were very strong and lasting, also baskets and kits of all sizes. Some of them were woven in regular patterns with black (dyed) and uncoloured flax, others were skillfully and pleasingly semi-damasked (if I may so term it) by changing sides to the flax leaves used to form the pattern, the upper side of the leaf being smooth and shining, the under side not shining and of a glaucous colour. The little kit, or basket, for a first-born child was often a little gem of weaving art, and made by the mother.

Besides the flax plant they had other fibrous plants whose leaves and fibres were also used in making articles of dress. (1) the *tou* (*Cordylone indivisa*), of which they made black everlasting wraps or cloaks. The making of these was confined to the natives of the mountainous interior, where alone those plants grow. (2) The long orange-coloured leaves of the *pingao* (*Desmoschanius spiralis*), a prostrate spreading sea side plant, also afforded them good materials for weaving useful folded belts, which were strong and looked and wore well, and were highly valued. (3) The climbing *kukie* (*Freycinetia banksii*) was also used, likewise the long, slender, and soft leaves of the *kahakaha* (*Astelia banksii*), but not frequently. (4) Of the leaves of the common swamp plant *saupo*=bulrush (*Typha angustifolia*), they formed large sails for their canoes. These leaves the Maoris curiously laced together. (5) I should not omit to mention their flying kites (*pakaukau* and *manuauke*), formerly in great esteem among them, and made of the manufactured bark of the *ant* shrub=paper mulberry (*Broussonetia papyrifera*), which was formerly cultivated by the ancient Maoris for its bark. Inferior ones, however, were made of the prepared leaves of some of the larger sedges. They were prettily made, requiring both time and skill in their construction, and much more resembled a bird flying than our English ones. They always served to remind me of those of the Chinese, as we see them in their own drawings and on their chinaware. The old chiefs would sometimes quietly spend hours amusing themselves in flying them and singing (*softo voce*) the kite's song, using a very long string.<sup>1</sup> Kites being flown at any village or fort was a sure sign of peace. These, too, gave rise to proverbs, some being quaint and highly expressive. A pleasing one I give as a sample "*He manuauke e taea te whakahoro*"=A flying kite made of paper-mulberry bark can be made to fly fast (away, by lengthening the cord). Used by a lover, expressive of impatience at not being able to get away to see the beloved one.

2. *Of their Spun Fibrous Articles*—These were very numerous in kind, size, and quality, according to the particular use for which they were required, and, while the larger number of them were composed of scraped and prepared flax-fibres there were also other fibrous leaved plants used by the Maoris, particularly the leaves of the erect cabbage-tree=*tu* (*Cordylone australis*) and of the *kukie*, already mentioned. Here, too, in this department, the different kinds of varieties of the flax would be used for making the different sorts of threads, cords, and ropes, some of the varieties of flax enduring much greater strain when scraped and spun into lines than others; and of such their deep-sea fishing-lines were made. It was ever to me an interesting sight to see an old chief diligently spinning such lines and cords—always done by hand, and on his bare thigh. The dexterity and rapidity with which he produced his long hanks and coils of twine and cord, keeping them regular, too, as to thickness, was truly wonderful. Some of their smallest twisted cords or threads were very fine. Such were used for binding on the barbs to their fishing hooks, and for binding the long queues of

be found here in New Zealand, is also used on the Continent of Europe for similar purposes. In some parts of Germany it is dedicated to the Virgin Mary (hence, too, its generic name of *Hieracium*=sacred grass), and is strewn before the doors of the churches on festival days as the *moet sedge* (*Acorus calamita*) is strewn on the floor of the cathedral at Norwich for the same purpose at such seasons.

<sup>1</sup> Sir James Hector, in his book on the *Phormium* plants, enumerates fifty five named varieties, but it is doubtful whether more than half of that number are permanent ones.

<sup>1</sup> See an interesting historical tradition respecting such (Trans. N.Z. Inst., vol. xiii, p. 48).

dog's hair to their chiefs' staffs. One of those peculiar cords was a very remarkable one, it was a small cord, bound closely round throughout its whole length with a much smaller one (something like the silver or fourth string of a violin). I never saw this kind but once, and that was at the East Cape, in 1838. A specimen of it I shall now exhibit. This cord was used for a single and particular purpose, attached to the small under-aprons of girls—chiefs' daughters.

Their larger cords and ropes were composed of several strands, well twisted and put together. Besides their round ropes so made, they had also flat ones of various widths, which were plaited or woven, resembling our webs and bands, and much used as shoulder straps in carrying back loads, also double twisted ropes, and three strand ones, likewise a remarkably strong one that was four sided. This was made of the unscraped leaves of the cabbage tree, that had been gathered, and carefully wilted in the shade, and then soaked in water to make them pliant. It was used for their anchors, and other heavy canoe and house requirements. The leaves of the flax would not be suitable for this purpose. I have had all those different kinds of cords and ropes made for me in former years, but I much fear the art of making them is lost.

There were also their nets for catching fish and for other purposes, with their meshes of various dimensions. Their smaller ones (hand nets) were made of all manner of shapes and sizes. Some of them were dexterously stretched over circular skeleton framework. And their large seine-nets, used for catching mackerel and other summer fish that swam in shoals, were very long and very strong, made of the leaves of flax, split and prepared, but not scraped, and completely fitted up with floats, and sinkers, and ropes, and other needful appurtenances. Cook, who was astonished at their length, has written much in praise of them. I make one striking quotation: "When we showed the natives our seine, which is such as the King's ships are generally furnished with, they laughed at it, and in triumph produced their own, which was indeed of an enormous size, and made of a kind of grass [*Phormium*] which is very strong. It was five fathoms deep, and by the room it took up could not be less than three or four hundred fathoms long" (Voyages, vol. ii., first voyage, pp. 369, 370).

In residing at Dannevirke, in the Forty-mile Bush district, during several months, I have often noticed the Maoris from neighbouring villages coming to the stores there to purchase tether and other ropes and lines (large and small) for their use with their horses, ploughs, carts, pigs, &c., while on their own lands and close to them the flax plants grew in abundance. These Maoris had very little to occupy their time, and could easily have made common lines and ropes for their own use if they knew how to spin them as their fathers did, and also possessed their forefathers' love of work.

### UGANDA

AT a special meeting of the Royal Geographical Society on the evening of November 3, Captain F. D. Lugard gave an account of the geographical aspects of his work in Uganda. The hall of the University of London was crowded, and although the issue of extra tickets was suspended, a large number of Fellows and their friends failed to get admittance. An excellent hand-map, by Mr. Ravenstein, enabled the audience to follow Captain Lugard's route. The first part of the paper was concerned with the journey from Mombasa along the Sabakhi river, an unnavigable stream, to Machako, the furthest station of the I. B. E. A. Company at that time, the district passed through being almost uninhabited, and supplies difficult to procure. The greater part of the paper related to Uganda and the other countries surrounding the Victoria Nyanza, where Captain Lugard was in command for two years. On the Kavirondo plateau, east of the lake, there is a promising field for European colonisation. The plateau is crossed by the Equator, but at elevations of from 7000 to 8000 feet the climate is cool and exhilarating. It is possible, judging from experience in other

places, that highlands close to the Equator are healthier for Europeans than those of similar mean climate lying nearer the tropics. Kavirondo is admirably adapted for grazing, and ranches similar to those of the west of America might be tried. From the pasture lands of this plateau the transition to the rich plantations of bananas and casava of Usoga and Uganda is very marked, and the unclothed natives of Kavirondo give place to the comfortably-dressed Waganda, a warlike people, but skilful in all the arts of peace.

Uganda is a land of low hills and valleys. The hills are of red marl, or marl gravel, and shale, generally covered with pasture grass of a kind apparently peculiar to these countries. The valleys are generally of rich black soil, and most frequently the lowest part of the dip is a river swamp. The swamp varies from a few score of yards to a mile or more in breadth, usually being from half to three quarters of a mile. There is a slight trickling current—but very slight, the river is choked with dense papyrus, with an undergrowth of marsh ferns, grass, reeds, &c. The water is usually the colour of coffee, and red with iron rust. Most of these swamps are of treacherous quagmire without bottom, and unless the roots of the papyrus form a sufficient foothold it is necessary to cut down reeds and boughs of trees to effect a crossing. It is a singular characteristic of these countries that, spite of their altitude and hilly character, rushing water is rarely, almost never, to be seen. Thus Uganda has a mean elevation of some 4200 feet, and borders the trough of the Victoria Nyanza at 3700 feet only, and is a country full of hills and valleys. Kitagwenda, at about the same altitude, borders the Albert Edward Lake at 3300 feet. Unyoro, with more lofty hills and peaks of granite, with an altitude gradually increasing in the south, as you near the Albert Lake, to some 5300 feet, similarly borders the trough of the Albert, which has an elevation of only 2000 feet. Yet nowhere are these river swamps more frequent than here in South Unyoro at the highest altitudes. The origin of the water to supply the enormous Lake Victoria is an interesting problem. Throughout the British sphere, on the north and west of the lake, there is no single river, except the Nzoia, which is worthy of the name flowing into the Victoria. The Katonga—marked on the maps as a big river—is merely a broad papyrus swamp. It is by no means so important a drainage as the Marengo, and all the endless river-swamps (including the Marengo) send their sluggish streams northwards to the Kafur and the Somerset Nile. The superficial area of the Victoria being 27,000 square miles, crossed by the Equator, and at an altitude of about 3800 feet, an enormous amount of evaporation must occur, and yet spite of this evaporation, there issues from its north-western corner the magnificent Somerset Nile, a deep, broad, silent river.

The close of the year 1891 and the early part of 1892 were exceptional in the matter of rainfall. Usually in this part of Africa the lesser rains begin early in October and cease in the middle of December. From that time the heat and drought increase, and the grass dries up and is burnt, till in the beginning of March the greater rains set in, and a tropical downpour continues with few breaks till the end of May. Last October and November the lesser rains were unusually heavy, and continued with little intermission till the time of the regular rains in March. There was a little check, and then the rain continued up to the middle of June and later. The result was, that the Lake Victoria was some six feet perhaps above its ordinary level, and may probably rise still higher. Unusual floods occurred in the Nile in Egypt during September, this not being the time at which the usual high Nile due to the Atbara floods occurs.

Uganda is divided into ten provinces, and the ten chiefs who rule these districts entirely drop their personal names, and are called by the traditional title attached to those provinces. Of these the four largest and most important have separate titles. Thus, the chief of Chagwe is the Sekibobo, of Singo, the Mukwenda, of Budda, the Pokino; and of Bulamwezi, the Kangao. The remaining six are called by the title of their province, viz. Kitunzi, Katambala, Kasuju, Mugema, Kago, and Kaima. Superior in rank to these ten governors of provinces are the Katikiro (the vizier and chief magistrate of Uganda), and the Kimbugwe. These two hold innumerable estates, scattered throughout the country.

In June, 1891, Captain Lugard left Uganda with the object of coming in touch with the Sudanese refugees from the Equatorial Province, who had assembled at Kavalli's, on the south-

\* An interesting historical tragic story of the cleverly-planned taking and death of a large number of Maoris in one of these seine-nets, together with the fish illustrating what Cook has written of their immense size, and of the deadly warfare that followed, is given in the Transactions N.Z. Institute vol. xiii., p. 43.

west shore of the Albert Lake. Marching from near Masaka, the capital of Buddu, he traversed Northern Ankole, a district hitherto unvisited by any European, though Mr Stanley, in 1876, had travelled parallel to it within the boundaries of Uganda, and reaching the borders of Kitagwenda, proceeded south-west to the narrow channel or river which connects the upper lake of Rusango with the main waters of the Albert Edward Lake. Crossing this narrow channel (at most 500 yards wide) the force camped in the hostile country of the Wasura, a tribe subject to Kabarega of Unyoro, and identified with the Wanyoro. Here they crossed Mr Stanley's route at the Salt Lake; but since his book nor maps had not then reached Central Africa the journey was in the nature of entirely new exploration, though of course the discovery of the Albert Edward Lake and of Ruwenzori had been anticipated. The natives, too, being hostile, no one was met with who had seen Mr Stanley, or could give information of his route, or tell of his exploits. On the route to the Albert Lake many deep and almost symmetrically circular depressions like the crater of a volcano, or a dried up pond, were passed. A few of these, as shown on the map, were tiny lakes no bigger than a mill-pond, but apparently of great depth, with clear blue water, and all the characteristics of a lake. The alligator and great fish eagle haunted their waters. Others, again, were dry, the bottoms being perhaps 100 feet or more below the level of the surrounding country, which is about 4200 feet above the sea.

The Lake Albert Edward consists of two portions, the Mwutan-zigé (Barrier to Locusts), or the Great Lake and the Rusango on the north east. This latter is in reality a separate lake, connected with Mwutan-zigé by a river. Its general direction is north-west and south-east. There is no swamp around it except at the north west end, where dense jungle and impenetrable marsh afford a home for great herds of elephant. It is at this point that the rivers Wami and Mpanga, into which the countless streams from Ruwenzori flow, bring their waters to the lake. The gorge through which the latter flows is picturesque in the extreme, especially in the rains. The great body of water confined between its rocky walls boils and eddies over the sunken rocks below. The gorge is some 700 feet deep, and is full of tropical forest. The orchids, ferns, and mosses which are found in such a natural forcing-house, where the damp vapours hang, are extremely luxuriant.

Captain Lugard followed the eastern base of the Ruwenzori Mountain, crossing the endless streams which descend from its perpetual snows, and hear their clear, sparkling, icy-cold water to the Wami and Mpanga, and so to the Albert Edward. The drainage of the eastern Ruwenzori is not towards the Albert and so to the Nile, but to the southern lake, from which the only overflow is the Semliki, a river which at its exit probably conveys a lesser volume of water from the Lake than is contributed to it by the Mpanga alone. The ground rises gradually from the level of the Albert Edward 3300 feet to some 5300 feet at Kiaya. Here the route descends into the head of a narrow valley, while the plateau trends away to the right, and forms the uplands of Unyoro, its bold outline appearing from the Semliki Valley and the Albert Lake like a lofty range of hills. The valley of Kiaya is extremely fertile, intersected with streams, and studded with banana groves and cultivated land. Between the edge of the plateau on the east and the base of Ruwenzori there is a deep trough, or gorge, the hills rising steep as it were from their own foundations without connection with the plateau, which reaches to their very feet. Leaving Kiaya, they passed through a wild country of quartz and scrub jungle, cut at right-angles by gigantic ravines of rich soil, in which are villages, forest, and cultivation. This led to the edge of a lower plateau, overlooking the Semliki valley. Simultaneously the massive peaks of Ruwenzori sloped down to lesser hills, and mingled with the plain, and a new range of mountains, increasing in height from south to north, appeared opposite. Mountains they appear, but, like those left behind, they are really the escarpment of the plateaus on which the sources of the Ituri, and the other great affluents of the Congo, take their rise, which, for convenience, may be called the Kavalli plateau. From Kavalli's Captain Lugard escorted 8000 Soudanese troops, who had by their vacillation retarded the departure of Stanley with Emin from the coast. Some of these he settled in forts to protect Uganda from Kabrega's raiders, while others were sent back to Egypt by Mombasa.

## SCIENTIFIC SERIALS

*American Meteorological Journal*, October.—A meteorological balloon ascent at Berlin by A. L. Rotch. The ascent was made on the morning of October 24, 1891, and at the same time a captive balloon was sent up to 600 metres. The weather was hazy up to about 1000 feet, but above that the sky was nearly clear. The mean decrease of temperature between the ground and the captive balloon was 0.6 C. per 100 metres. In the stratum of air between the captive and free balloon (700 to 1000 metres) the decrease was much slower during the morning, there being at first an increase, the temperature at 693 metres was 10° C., and at 858 metres 10° 4'. In the afternoon the rate of decrease in the upper stratum became nearly the same as that which prevailed in the lower stratum during the morning.—Improvement of weather forecasts, by Prof. H. A. Hazen. The author recommends the study of moisture conditions at various heights in the atmosphere, and considers that the greatest hope of improvement is in the observation of atmospheric electricity.—The storms of India, by S. M. Ballou. The storms are divided into three classes: (1) the cyclones that occur at the changes of the monsoons, (2) the storms of the summer rains, (3) the winter rains of the northern provinces, he discusses the causes of their formation, and gives a brief description of each of these classes.—The ether and its relation to the aurora, by E. A. Deale. The author gives a brief summary of some of the facts respecting our knowledge of auroras, in view of their probable maximum during the coming year in connection with their correlation with frequency of sunspots.—There are also short articles on warm and cold seasons, by H. Gawthrop, facts about rain making, by G. E. Curtis, and convectional whirls, by Prof. H. A. Hazen.

## SOCIETIES AND ACADEMIES

### LONDON

Anthropological Institute, October 18.—A special meeting was held, the president, Edward B. Tylor, D.C.L., F.R.S., in the chair, to receive a communication from Major R. C. Temple, I.S.C., on "Developments in Buddhist Architecture and Symbolism as illustrated by the Author's Recent Exploration of Caves in Burma." Major Temple commenced by saying that the object of the paper was chiefly to draw attention to the extraordinarily rich and for the present practically untouched field for the ethnographer and antiquary existing in Burma. He exhibited some photographs of life size figures in wood, carved by a well known artist of Maulmain, of the "four sights" shown to Buddha as Prince Siddhartha on his first visits to the outer world, viz., the old man, the sick man, the dead man, and the priest; and also some admirable gilt wooden representations from Rangoon of Buddha in his standing and recumbent postures, with his begging bowl, and seated as King Jambupati, surrounded by priests and other worshippers. He next showed a remarkable set of gilt wooden images from the platform of the great Shwedagon pagoda at Rangoon, of *nats*, *belus*, *hanuman myauks*, and other spirits believed in by the Burmese, seated on the steps of a lofty *tagon-dain*, or post, on the top of which is always perched the figure of the *henth* (*hansu*), or sacred goose, which apparently protects pagodas in some way. From these he passed on to four representations of large glazed bricks or tiles from Pegu. These curious, and (so far as English museums are concerned) probably unique antiquities may be presumed to be at least 400 years old, and formed at one time the ornamentation of the three procession paths round a now completely ruined pagoda. They represent the march, battle, and flight of some foreign army, represented in true Indian fashion with elephant, monkey, and other animal faces. Some of the figures are clad in Siamese and Cambodian fashion. The glazing is remarkably good, and Indian influence is clear in their construction. They may probably represent a scene from the *Ramayana*, which in a mutilated form is well known to Burmese mythology. These were followed by a huge figure of Buddha from Pegu, in his recumbent attitude, which may be referred to King Dhammazedi, who flourished in the fifteenth century. This image is 181 feet long and 46 feet high at the shoulder. It is built of brick, and is well proportioned throughout. Its history is lost, and so was the image itself until 1881. Pegu was utterly destroyed about 1760 by the Burmese,

and the interest in its holy places lost for more than a generation. This image became jungle grown and hidden from view, and was accidentally discovered by a railway contractor searching for ballast for the line in the neighbourhood. General and detailed views of the Kawgun Cave were shown, exhibiting the wonderful extent of its decoration by a vast number of terra cotta tablets and images in wood, marble, alabaster, and other materials, and the extraordinary variety and multitude of the objects connected with Buddhistic worship, both ancient and modern, to be found in it. The Kawgun Cave is the richest of those visited by Major Temple, but he explained that he had examined about half a dozen others in the district, and had since gathered positive information from local native sources of the existence of about forty altogether. Many of these are hardly inferior to Kawgun in richness of Buddhistic remains, and several are said to contain in addition ancient MSS., which must now be of inestimable value. A few such MSS. have actually been found. It will thus be seen how great and valuable is the field, and how well worth systematic study by competent students.

**Royal Microscopical Society, October 19.**—Mr G. C. Karop, Vice president, in the chair.—The chairman exhibited and described Messrs. Swift's aluminium microscope, which he believed to be the first microscope made of that metal. The chief point in the instrument was its extreme lightness, the whole when complete, and including the condenser and eyepiece, weighing only 2½ lb 10½ oz as against the weight 7½ lb 13 oz of a precisely similar stand made in the usual way of brass. It was perhaps not entirely correct to say that every portion was of aluminium, because there were certain mechanical difficulties met with which prevented some portions from being made of that metal, for instance, he believed it was almost impossible to cut a fine screw upon it without the thread "stripping," and it was also found extremely difficult to solder, so that the necessary screws in the instrument were made of brass, the Campbell fine adjustment of steel, the rack and pinion coarse adjustment was also not made of aluminium, and the nose piece was of German silver.—Prof. F. Jeffery Bell read a letter received from Mr H. G. A. Wright, of Sydney, stating that a scale of Podura in his possession was deeply notched, and that an exclamation mark had become detached and projected from the edge. Mr Wright also sent photomicrographs to support his statement. The chairman said he could not be sure, from the cursory examination he had been able to make, that the exclamation mark referred to was to be seen.—Dr C. E. Beevor read a paper on methods of staining medullated nerve-fibres, illustrating the subject by photomicrographs, and by a number of preparations under microscopes. The chairman said they were very much indebted to Dr Beevor for his interesting paper. It was a good thing to be able to differentiate nerve fibres in the ways described, but it was a pity that they could not also so differentiate them as to show from which part of the nervous system they came. If this could be done he need hardly say it would be of great value.—Prof. Bell read a paper by Dr H. G. Piffard on the use of monochromatic yellow light in photomicrography. Mr T. Charters White said that he had himself tried a similar process with monochromatic light obtained by using screens and solutions, but the chief difference he found was that it very much prolonged the time necessary for exposure. Mr T. Haughton Gill said that he had used the copper light filter for the same purpose, and had found that by its aid any good ordinary lens would give as good results as were otherwise obtained by using an expensive apochromatic, because it filtered off all the rays except those which were visually strong. He had not found, in the course of his work, that the use of this light prolonged the exposure, that was to say, that with a magnifying power of X300 and an exposure of ten minutes, he could get a good strong printing image with the isochromatic plates.—Mr G. Massee's paper on *Heterosporium isoperlatum*, a parasitic fungus, was, in the absence of the author, taken as read.

**Zoological Society, November 2, Frederick DuCane Godman, F.R.S., president, in the chair.**—Mr S. Stevens exhibited, for Mr J. Harrison, a beautiful series of *Arctia lubricipeda* var. *radiata*, which had been bred by Mr Harrison this year.—Mr G. T. Bethune-Baker exhibited specimens of *Polyommatus dispar* var. *rufulus*, taken in England by his father about sixty years ago. He stated that it was generally believed that this form of the species was confined to the Continent, but his specimens proved that it formerly occurred in England.—Mr C. G. Barrett exhibited dark varieties of *Acronycta leporina*,

bred by Mr J. Collins, also a white variety of *Triphana prouba*, taken at Swansea.—Mr M. Jacoby exhibited a specimen of *Sagra femorata*, from India, with differently sculptured elytra, one being rough and the other smooth.—Mr J. A. Clark exhibited a long series of remarkable varieties of *Liparis monacha*, bred from two specimens taken at Scarborough. Several of the specimens were as light in colour as the typical form of the species, others were quite black, and others intermediate between these two extremes.—The Rev. Seymour St. John exhibited a monstrosity of *Abiaxas grossularata*, and a specimen of *Tentocampa stabilis*, with a distinct light band bordering the hind margin of the upper wings.—Mr E. B. Poulton, F.R.S., exhibited two series of imagoes of *Guophos obscurata*, which had been subjected to dark and light surroundings respectively. The results were seen to be completely negative, the two series being equally light.—Mr F. Merrifield showed a number of pupæ of *Pieris napi*. About eight of them, which had attached themselves to the leaves of the cabbage plant on which they were fed, were of a uniform bright green colour, with light yellowish edgings, of the others, those which had attached themselves to the black net covering the pot, or the brownish twigs which supported it, were dark coloured, with dark spots and lines. Mr R. Adkin exhibited three bred female specimens of *Panassa c. album*, two of which belonged to the first brood, and the third to the second brood. One of the specimens of the first brood was remarkable in having the under side of a very dark colour, identical with typical specimens of the second brood. He thought the peculiarity of colouring had been caused by a retarded emergence, due to low temperature and absence of sunshine.—Mr F. W. Frohawk exhibited varieties of *Satyrus hypocranthus*, bred from ova laid by a female taken in the New Forest in July last.—Mr F. D. Godman, F.R.S., exhibited a specimen of *Amphonyx medon*, Cr., received from Jalapa, Mexico, having a pouch-like excrescence at the apex of its body.—Mr C. J. Gahan communicated a paper entitled "Additions to the Longicornia of Mexico and Central America, with notes on some previously recorded species."—Mr W. L. Distant communicated a paper entitled "Contributions to a knowledge of the Homopterous family Fulgoridæ."—Mr Oswald Latter read a paper (which was illustrated by the Society's new oxy-hydrogen lantern) entitled "The Secretion of Potassium-hydroxide by *Dicranura vinula*, and the emergence of the imago from the cocoon." The author stated that the imago produced, probably from the mouth, a solution of caustic potash for the purpose of softening the cocoon. The solution was obtained for analysis by causing the moths to perforate artificial cocoons made of filter-paper. Prof. Meldola, F.R.S., said that the larva of *D. vinula* secretes formic acid, and Mr Latter had now shown that the imago secretes potassium hydroxide, a strong alkali. He stated that the fact that any animal secreted a strong caustic alkali was a new one. Mr Merrifield, Mr Hanbury, Mr Gahan, Mr Poulton, and Prof. Meldola continued the discussion.—Mr H. J. Elwes and Mr J. Edwards read a paper (also illustrated by the oxy-hydrogen lantern) entitled "A revision of the genus *Ypthima*, principally founded on the form of the genitalia in the male sex." Mr McLachlan, F.R.S., said he attached great importance to the genitalia as structural characters in determining species, and he believed that he could name almost any species of European Trichoptera simply from an examination of the detached abdomens of the males. Mr O. Salvén, F.R.S., said he had examined the genitalia of a large number of Hesperidæ, with the view of considering their value in distinguishing species. Mr Bethune-Baker, Colonel Swinhoe, Mr Lewis, Dr Sharp, F.R.S., Mr Hampson, and Mr Champion continued the discussion.—Mr S. H. Scudder communicated a paper entitled "New light on the formation of the abdominal pouch in *Parnassius*." Mr Elwes said he had based his classification of the species of this genus largely on the structure of this abdominal pouch in the female. Mr Jenner-Weir remarked that a similar abdominal pouch was to be found in the genus *Acraea*, and Mr Hampson referred to a male and female of *Parnassius* in Mr Leech's collection, in which the pouch had come away from the female and was adhering to the male organs.

**Academy of Sciences, October 31.**—On the geometry of position, by M. H. Poincaré.—Observations on M. Berthelot's communication regarding the fixation of nitrogen, by M. Th.

Schlossing Reply, by M Berthelot—On the laws of compressibility of liquids, by M E H Amagat Deformations of the piezometers were investigated and allowed for in these experiments, and the pressures carried as far as 3000 atmospheres. The liquids operated upon were ether, alcohol, carbon bisulphide, acetone, the ethyl halides, and chloride of phosphorus. In every case the coefficient of compressibility was found to decrease regularly as the pressure increased. At 3000 atmospheres that of water was reduced by nearly one half its ordinary value, that of ether by two-thirds. This diminution again is greater the higher the temperature. The ratio of the difference of the coefficient to the corresponding difference of temperature,  $\frac{\Delta\mu}{\Delta t}$ , increases rapidly with the temperature, and decreases rapidly as the pressure increases. The value of  $\frac{\Delta\mu}{\Delta t}$  also diminishes rapidly as the pressure increases, but whilst for alcohol it grows decidedly with the temperature, for ether it seems sensibly independent of it. It is probable that the ratio passes through a maximum at a certain temperature.—Observation of the comet Barnard (October 12), made at the Algiers observatory with the equatorial circle, by M F Sy.—Elliptic elements of the comet Barnard, by M Schulhof. Discussing the probabilities of the new comet being identical with, or a part of, the comet Wolf, which was subjected to considerable perturbations by Jupiter in 1875.—On the equations of dynamics, by M R Liouville.—On the solution of the ballistic problem, by M E Vallier.—Displacements of a magnet on mercury under the action of an electric current, by M C Decharme. If a light magnetic needle be floated on a bath of perfectly pure mercury, and conductors carrying a current be dipped into the mercury at different places, the needle will, before assuming the position of equilibrium according to Ampère's law, go through a series of excursions, rendered necessary by the difficulty of its motion, perpendicular to its length. If the current crosses the mercury in a direction perpendicular to the length of the needle for instance, with the negative pole of the current on the left of the south-seeking pole, the needle will move away parallel to itself, will turn round, and return to take up the normal position.—On the temperature of maximum density of mixtures of alcohol and water, by M L de Coppet. The lowering of the freezing-point in solutions of alcohol is sensibly proportional to the quantity of alcohol, in confirmation of Blagden's law. But the lowering of the temperature of maximum density is not proportional to the percentage of alcohol. For weak solutions there is no lowering, but rather an elevation of the temperature of the maximum.—On the dissociation of barium dioxide, by M H. Le Chatelier.—On a limited reaction, by M Albert Colson.—On the fixation of free nitrogen by plants, by MM Th Schlossing, jun, and Em Laurent.—Purification of drain waters by ferric sulphate, by MM A. and P Buisine.—Experiments on bread and biscuit, by M. ## THE GEOLOGY OF SCOTLAND

*Geological Map of Scotland* By Sir Archibald Geikie, D.Sc., I.L.D., F.R.S., Director-General of the Geological Survey of Great Britain and Ireland. With descriptive text (Edinburgh J. Bartholomew and Co., 1892)

HERE have been many attempts to frame a popular definition of man. To call him a "story-loving animal" would not be the worst of them. It may indeed turn out when we understand monkey-talk a little better than now (and the hope that we may is, we are assured, not unreasonable), then it may be that this will prove to be not an exclusive definition. But this by the way, the description will hold for the present. Hence the delight with which we listen to all that the various branches of history, the history of the growth of knowledge included, have to tell us. It is the stories which first attract us, and they retain their charm long after we have learned that the study of history has other ends to fulfil besides the satisfaction of that craving for story-hearing which lies deep in our being, and the gratification of a natural curiosity to learn about things which we have not seen. But the conviction that history should be to us something more than a string of anecdotes soon forces itself upon us.

In tracing the growth of any branch of knowledge, in noting the steps by which, one by one, each advance has been made good, our interest lies first of all in the acquaintance, almost of a personal character we may say, which we make with the pioneers of a movement of which we see not perhaps the full development but the ripening fruit. We watch with absorbed attention their approach to the unexplored land, we follow them along the tracks by which they first traversed it, we stand by while they note and record all that is novel and characteristic in its features, we mark the birth and growth of the conceptions which their exploring work gives rise to, we live over again their fascinating life of discovery and deduction. But beside and beyond all this, their story, like the stories of all history, carries with it a lesson, and their caution or rashness, as the case may be, in generalizing and drawing conclusions, serves as example or warning to us. We look up to candour and a readiness to court criticism and give up explanations which are shown to be untenable, anything like partizanship and a weakly parental predilection for the children of one's own brain we look down upon with sorrowing pity.

The history of the steps by which a knowledge of the geology of a country has been arrived at is written in the successive versions of its geological maps. The appearance of a map which embodies the results of the latest researches into the geology of Scotland tempts us to look back upon the earlier efforts to unravel the complications of its geological structure. And this all the more because we are dealing with a country in which Geology, as we know it, may be said to have come to the birth; and because it is to Scotchmen that we owe the first showing forth of these principles, whether of observation, deduction, or inductive confirmation, which have been the guide

of geologists ever since. To Hutton, the precursor of Lyell, to Hall, the scientific ancestor of Daubrée, and to the line of illustrious followers who have carried on with such brilliant success the work which they started.

Among the earliest attempts to deal with the geological mapping of Scotland are the maps of Macculloch's "Western Islands," which bear the date of 1819. It is hard for us to realize how much of Scotland was at that time without adequate topographical delineation. Our present Ordnance Maps are far from being a credit to the Department which issues them, and the language which attends an attempt to use them on the mountainous moorlands, though not a whit stronger than is justifiable under the circumstances, had better be left to melt into thin air around the spots where it was uttered. But our geological life is one of luxury compared with Macculloch's, whose atlas is one string of apologies for the inadequate maps on which he had to record his observations. The map of the Isle of Man "is obviously very inaccurate, but there was only a choice between it and two others equally unworthy of confidence." The map of Staffa "was drawn under every unfavourable circumstance, and cannot fail to be inaccurate, having been merely paced with the assistance of a pocket compass in a severe gale of wind and rain."

Macculloch seems to have projected, but never completed, a geological map of the whole of Scotland. The materials collected by him were however utilized by the Highland Society in the construction of a general map in 1832.

Passing by the maps of Boué, and a sketch of Murchison's and Sedgwick's, laid before the Geological Society in 1828, we come to the publication of Nicol's "Guide to the Geology of Scotland" in 1844.

In a country where the rocks are so largely unfossiliferous, it is natural, even necessary, that the earliest geological maps should be more of a lithological than a stratigraphical character, and this is the case with the maps so far noticed. In the map which accompanies Nicol's guide, and which he says is based on Macculloch's, some of the main varieties of the crystalline schists are distinguished, but the order in which they occur is not indicated. One colour comprises all the red sandstones, the Torridon, the Old Red, and even the red rocks of Dumfriesshire, under the head of "Porphyry and Trap" are lumped together all the volcanic rocks, including those of the western islands and of the central valley, only two of the groups which we now call formations are separated, the "Carboniferous" and the "Lias and Oolite." But the great leading features in the physical geography of Scotland are sharply marked out, the three regions into which it naturally falls are lucidly delineated, and the work is crowded with local details that betoken acquaintance with the work of others and patient investigation of his own.

At the meeting of the British Association at Glasgow in 1855 Murchison gave an account of the result of the joint work of Nicol and himself in the north western Highlands. The existence of three great sub-divisions had been clearly established; what we now know as the Hebridean or Lewisian Gneiss at the base, the Torridon sandstone resting unconformably on it; while above that, and separated from it by another unconformity, came the

limestones and quartzites of Durness and Loch Erriboll, in which Peach had recently discovered fossils. The last group appeared to be conformably overlaid by a great mass of crystalline schists, which came to be known afterwards as the "Upper or Eastern Gneiss." Though the fossil evidence was then incomplete, Murchison saw nothing in it to forbid the belief that the Durness beds were of Lower Silurian age, and his conjecture was confirmed by the discovery of better specimens. This conclusion was announced in a paper read before the Geological Society in 1858, in which it was also stated that the author looked upon the Upper Gneiss as metamorphosed Silurian.

In the meantime Nicol had read a paper before the Geological Society (1856), in which he describes the joint explorations of himself and Murchison, and some subsequent work of his own. He recognizes the same main sub-divisions as Murchison, but still leans to the old notion that the Torridon sandstone belongs to the Old Red, this involves the assigning a later date to the Durness Beds, and these he thinks may be Carboniferous. But he is content to hold this merely as a provisional hypothesis till further fossil evidence is forthcoming. With respect to the Upper Gneiss he is very cautious, suggesting that it may be a newer metamorphic group, or may be merely a portion of the lower, that is Hebridean, *gneiss forced up by some great convulsion*. This latter solution was evidently present very vividly to his mind, for it is repeated, as a possible explanation, no less than three times.

Here a very important difference of opinion between Murchison and Nicol makes its appearance.

It was probably about this time, but the map bears no date, that Nicol issued a new geological map of Scotland. In this all gneiss is denoted by one colour, but the explanation states that the author does not consider all the Scotch gneiss to be of the same age, that the tract of this rock, with associated quartzite and limestone, stretching from Aberdeenshire through Perthshire to the Breadalbane Highlands of Argyllshire, may be a newer formation; while he is disposed to look upon the great mass of gneiss, extending from the north coast of Sutherland southwards through Ross-shire and Inverness-shire, rather as belonging to an older period. The Torridon sandstone is distinguished by a separate colour, though the author is still inclined to class it with the Old Red.

Nicol expounded his views to the British Association at Aberdeen in 1859, and again in a paper read before the Geological Society in 1860. He adduces many reasons for doubting the existence of an "upward conformable succession" from the Durness Beds to the Upper Gneiss, and explains the sections on the supposition that this rock is the Hebridean Gneiss brought up by faults. Though the expressions, "*forced up by convulsion*" and "*pushed up over*," which he uses in his paper of 1856, seem to show that the notion of what we call "Thrust Planes" was present to his mind, the sections of this paper hardly bear out that inference. He neatly twists Murchison with failing to see that the principles which he had applied with such success to an explanation of the structure of the Alps were equally applicable to the North-west Highlands. In 1861 Murchison stoutly maintained his view regarding the Upper Gneiss; with an ad-

vocate's skill he hits Nicol hard on his weak point, justly urging "that local interferences of eruptive rock nowise set aside broad data." In the same year was issued the "First Sketch of a new geological map of Scotland by Sir R. I. Murchison and A. (now Sir A.) Geikie," in which Murchison's views were adopted.

Here then was a promise of a fair stand-up fight between two champions, each well able to hold his own. But the promise was not fulfilled. The combat would have been far from equal. On the one side there were the pull which wealth and social position bring with them, the advantage which accrues from living in London and having thus the ear of a great centre of scientific life, and that pushing ambition, that eagerness to secure precedence in discovery, which so often go along with an active and energetic disposition. On the other side there were comparative social insignificance, residence in a hyperborean region far more difficult of access than now, a happy indifference to fame based on a confidence that the settlement might be safely left to time, and that the world would go on pretty much as heretofore, whichever of the two turned out to be nearer the truth. More than all a reluctance to embitter the closing years of life with anything that looked like an altercation with an old and esteemed friend and fellow-worker. So, because it takes two to make a quarrel, the fight never came off. Naturally, under these circumstances, (and can we blame it?) the world took the man who vigorously pushed his views, at his word, he had plenty to say in their favour and said it well, no one gainsaid him, his contention was accepted. There will be those who, without presuming to blame, do not covet success on such terms, and whose sympathies go out towards the peace-loving old man who was content to bide his time and possess his soul in silence.

And so the "Upper Gneiss" and "the upward conformable succession" held their own, and in the geological map of Scotland, issued in 1876 by the present Director-General of the Geological Survey, the crystalline schists of the Central Highlands are designated "Metamorphosed Lower Silurian." It would be tedious to enumerate all the points in which this map is an improvement on the "First Sketch" of 1861, but the student will find it an instructive exercise to compare the two maps, and ascertain by reference to memoirs on special districts how each correction and addition was arrived at.

The Highland problem remained in abeyance for nigh a quarter of a century, though during that interval the minds of many geologists were constantly recurring to it and evidence was being accumulated to help towards its solution. But it came to the front again, and like a giant refreshed with sleep, when Prof. Lapworth in his "Secret of the Highlands" (1883), and other workers in the same ground, began to throw doubt on the explanation which had so long held the field. When the Geological Survey were able to take up the question and work out the ground with precision and detail that no observer could attain to single handed, the anticipations of their immediate predecessors were substantially confirmed, and of the earlier observers it came out that Nicol was nearer the truth than his illustrious antagonist.

It calls for no small exercise of judgment, in an endeavour to depict the geology of so complex a district on

a map of small scale, to decide what details must be retained because they are essential to a grasp of its broad general structure, and what may be safely eliminated without impairing the comprehensive view. In the map now before us this end has been compassed with consummate skill. It bristles with detail, but there is nowhere crowding, the colours are well contrasted, and so transparent that they do not hide the topography, which is full and clearly printed.

The richness in detail of the strip of country between Cape Wrath and Loch Torridon marks one scene of the recent work of the Geological Survey. Then follows a broad band of "gneissose and schistose rocks not yet differentiated." A portion of this ground is occupied by the crushed and mangled-out complex of the "Moine schists," but a large part is yet imperfectly explored. To the south-east of the Great Glen we enter again on ground which has been largely worked out by the Geological Survey. We have here a group of various sedimentary deposits in a more or less altered condition, containing sheets of basic igneous rocks. The geological age of this series is not known, and they are provisionally classed as Dalradian.

The presentation of the results of the work of the Geological Survey in the north-west and central Highlands are the two most conspicuous novelties in the map, but during its use other corrections and additions, too small to catch the eye on a general view, become noticeable. In the explanatory notes we have a concise summary of the geology of Scotland, and feel that our thanks are due to the author for having put so much into so small a space without in any way sacrificing descriptive clearness. When the time comes for a new version of the map, may the same hand be with us to draw it up.

A. H. GREEN

### MEDICAL MICROSCOPY

*Medical Microscopy*. A Guide to the Use of the Microscope in Medical Practice. By Frank J. Wethered. M.D. (Lond.), &c. With Illustrations. Pp. 412. (London: H. K. Lewis, 1892.)

THIS volume, one of Lewis's practical series, bears an ambitious title, and must necessarily traverse a wide and intricate field of medical work. Its appearance is justified by the distinct need existing at the present time for a manual dealing with the various microscopical methods so essential to diagnostic accuracy and rational treatment.

The subject-matter is arranged in twenty-four chapters, and as an indication of the scope of the book, we instance some of the headings. The earlier ones treat of the microscope and its accessories, the methods of hardening, decalcifying, embedding, section cutting, staining, and injection of tissues. Then follow others on the examination of tissues, urinary deposits, blood, expectoration, and the detection of micro-organisms, and cutaneous parasites; while the latter chapters deal with the examination of food, water, and with bacteriological methods. In fact, the book is almost an epitome of the course pursued by a student earnestly working with the microscope from the commencement to the end of his

curriculum. The tendency has been, by the specialized character of the primary examinations in late years, to sever in some degree the knowledge obtained in the earlier part of a student's career from the practical application of the same at the bedside. So much is this the case, that it has been deemed advisable in some quarters to introduce new courses of lectures, their aim being to indicate with precision to students those facts in anatomy and physiology which have a distinct clinical value. One of the chief merits of Dr. Wethered's book is that he has therein demonstrated the important relationship between histology and morbid anatomy, and has shown that any attempt at acquiring a knowledge of the latter is dependent upon a practical and searching training in the former.

Moreover, the book is worthy of more detailed criticism. Necessarily in a first edition there are some points omitted. In speaking of the microscope the author offers a cursory remark on the fine adjustment, no mention is made of the best pattern, and there are many of an inferior and useless description foisted on students, nor are there any directions for the precise use of this portion of the microscope. In the chapter on "Hardening and Decalcifying Tissues," on p. 35, are found some well-meant platitudes on the necessity of immediately labelling specimens, but at the same time the use of lactic acid as a decalcifying agent is omitted. We have succeeded in completely softening small pieces of bone in 4-7 days, and teeth may be cut with the freezing microtome in from two to three weeks.

With certain statements of the author we venture to disagree. In speaking of the celloidin method he advises that the specimen be placed in equal parts of ether and alcohol previously to being placed in celloidin. A mixture of four parts of ether and one part of absolute alcohol ensures more rapid and complete penetration of the embedding material. Also in using paraffin for this purpose we have found by extensive practice that sections containing a large amount of fibrous tissue are useless after being in the paraffin bath for three to five hours, even at a temperature of 48° C., twenty to thirty minutes is ample, provided that the material is properly dehydrated. The chapter on staining is succinct and comprehensive, and we note the usual and indeed only rational classification of stains, as nuclear, general, and selective. Hæmatoxylin still holds the first place, and Delafield's, or as it is miscalled, Grenacher's, is undoubtedly the best formula. It is here stated that if the sections be overstained, and washing in acid-alcohol be necessary, the colour is not permanent. Our experience is that if after the acid they be washed thoroughly well with "tap water," a very clear nuclear stain results which remains unchanged for years. Gram's method of staining for micro-organisms, with Weigert's modification, is clearly detailed. But here we fail to observe any mention of the brilliant results obtained by the Ehrlich-Biondi method. The employment of rubin for actinomycosis may with confidence be recommended, and the same remark applies to the use of safranin in bringing out clearly the nuclear figures in karyokinesis. The chapter on mounting is somewhat tedious and the use of origanum oil in clearing celloidin-specimens is not advocated, although it has found general acceptance in Continental laboratories.

Weigert's method of preparing and staining nerve-tissue is given, but with one important detail left out, viz., that on removing the specimen from Muller's fluid or chromic acid solution it should have a brown, and not a green colour. The preparation of individual tissues and organs is well dealt with in chapter xii, but in the succeeding one on the examination of tumours there are such evident signs of hasty composition as to render it of small intrinsic value. On the other hand, the important subjects of urinary and excrementitious matters receive ample treatment; and we have a clear *résumé* up to this date of all that is taught on these subjects. As an example we note with pleasure the account of Dr. Delepine's work on "sable intestinal." The bacillus of Asiatic cholera and the methods of its detection are described on p. 228, and the diagnostic points between it and that of cholera nostras are found on the next page. A large amount of space is necessarily devoted to the examination of sputa. Dr. Wethered's experience at the City of London Hospital for Diseases of the Chest enables him to speak with the voice of authority on the signification of the presence or absence of the tubercle bacillus. Physiologists will find their side of the question well considered in the observations on blood, on Dr. A. Garrod's authority we are told that the blood of the Londoner has not yet been found to contain its true proportion of hæmoglobin. Eosinophile cells are not omitted; but for more detailed information on this point we commend to the notice of pathologists the article by Dr. A. Kanthack in the *British Medical Journal* of June, 1892.

Medical microscopy as a subject is exceedingly elastic, and we believe Dr. Wethered has stretched it to its widest limits when he finds space for describing the examination of various kinds of cereals, also of water. Even the homely tea-leaf has not escaped his notice. A few instances of clerical errors are to be found, thus Hartnack for Hartnack, on p. 122, Richert for Reichert. At the term "collodionization" we venture to express our distaste. A growing practice exists of introducing ungainly expressions of doubtful expediency into scientific works.

We have read this book with considerable attention, and are convinced that it has a most distinct *raison d'être*, and justifies on the whole, by the merit of its execution, the ambition of its title. It treats of the matter in hand with much ability, and in a manner that evidences considerable experience on the part of the author as a pathologist, physician, and teacher.

A. H. TUBBY

#### ODOROGRAPHIA

*Odorographia. a Natural History of Raw Materials and Drugs used in the Perfume Industry* By J. Ch. Sawer, F.L.S. (London Gurney and Jackson, 1892)

CONSIDERING the importance of the subject of perfumes both from a scientific and a commercial point of view, it is somewhat surprising that a really good and authoritative book dealing on the matters encompassed by "Odorographia" has not before been attempted. The delay in the appearance of such a work

is probably due to the fact that but few persons possess the requisite knowledge to treat the subject in a thoroughly satisfactory manner in all its bearings, such as the origin and production of the numerous products, whether animal or vegetable, and the chemical aspect of every substance and its commercial value, which are points that could scarcely be expected to be mastered by one mind. In the "Pharmacographia" of Flückiger and Hanbury, two master minds on the subject of drugs were brought into co-operation, with the result that a most satisfactory and standard work on medicinal plants was produced. That this book was in the mind of the author when he compiled his "Odorographia," and selected its title, is quite apparent, and we are bound to say that on the whole he has done his work remarkably well, though we wish that he had adhered more strictly to the lines of his pattern. Mr. Sawer, however, at the very commencement of his preface, is so modest as to say that "an endeavour has here been made to collect together into one manual the information which has hitherto been only obtainable by reference to an immense number of works and journals, English and foreign, in many cases inaccessible to readers interested in the subject," and that he is thoroughly well acquainted with all that has been written is apparent not only from a glance through the pages, where numerous references occur, but also from the "List of Principal Works referred to." Besides this the author has, as he tells us, obtained information first hand from some of the largest perfume-plant growers and manufacturers of Grasse, Nice, and localities in the Straits Settlements and West Indies. The difficulties attending the compilation of a work of this nature have, no doubt, been very great, because scraps of information are so widely dispersed, and even when found often-times very confusing. The botany alone of the subject must have occupied a considerable amount of time in looking up, the plants yielding perfumes being natives of various parts of the globe, and consequently described in the several floras appertaining to those special countries, besides which the chemical and commercial aspects occupy a large portion of the book.

Though we are grateful to Mr. Sawer for giving us a book that was really wanted, we regret, as we said before, that he has not followed more closely the plan of the "Pharmacographia" and arranged his matter under distinct heads, such as History, Botany, Cultivation, Chemistry, Commerce, &c. Practically he has done so to a certain extent, but the paragraphs are not sufficiently distinguished to enable one to turn at once to that upon which information may be specially sought. The arrangement of chapters, in which the most important and marked odours, such as those of musk, rose, violet, the citrine odours, &c., are brought together, is good, but the principal plants in each of these groups might have been treated as we have described, the least important ones being given as they are at the end of the chapters.

Returning to the botany of the book, we cannot but think that the author might well have spared much space by the omission of numerous varietal names and synonyms, many of which are scarcely ever heard of now, and which often only tend to confusion. Under Violet, for instance (p. 104), half a page is given to a list

of the names of nine varieties of the Sweet Violet (*Viola odorata*). Again, at p. 309, Vétiver, or Cus Cus, is rightly described as the root of *Andropogon muricatus*, after which follow the names of five synonyms. In reference to this Mr. Sawyer says, referring to the "Asiatic Researches," that "there is a verse in the Sanskrit language composed of nine words, arranged in two lines, purporting to be the nine names under which the plant was known, doubtless they were poetical names, as they are not found in the extensive list of local names recently enumerated by Watt." This would show that Dr. Watt, who in his "Dictionary of the Economic Products of India" does not err on the score of brevity in the adoption of synonyms, considered that there was a line to be drawn somewhere. We may perhaps also be allowed to draw attention to a paragraph on page 19, where the musk tree of Jamaica and the muskwood of Australia have got confused. The paragraph in question runs thus: "The *Eurybia argophylla* or *Guarea Swartzii*, the silver-leaved musk tree of Jamaica, New South Wales, and Tasmania, is a meliaceous tree, attaining a height of twenty-five feet." *Eurybia*, or more properly *Olearea argophylla* is the muskwood of New South Wales and Tasmania, and belongs to the natural order Compositæ, while *Guarea Swartzii* is a meliaceous tree of Jamaica, where it is known as musk tree. Another muskwood, not mentioned by Mr. Sawyer, is that of *Moschoxylum Swartzii*, a highly fragrant resinous tree, closely allied to *Guarea*, and a native also of Jamaica and Trinidad. We refer to these matters in no captious spirit, but simply with the hope that Mr. Sawyer may see his way to overhaul and modify this part of his useful book in a future edition, so as to make it even more useful and trustworthy. We are glad to note that he "is still engaged upon studies in this department, and hopes to publish another volume in due course."

#### OUR BOOK SHELF

*Catalogue of Eastern and Australian Lepidoptera Heterocera in the Collection of the Oxford University Museum.* By Colonel C. Swinhoe. Part I. Sphingids and Bombyces. (Clarendon Press, 1892.)

THIS volume is the first part of a Catalogue of the moths from the Oriental and Australian regions in the collection of the late Mr. W. W. Saunders, which was acquired by the Oxford Museum some fifteen years ago, and consists chiefly of specimens collected by Wallace during his famous voyage to the Malay Archipelago, and described by the late Francis Walker in his British Museum Catalogue. Since Walker's arrangement of the collection it has remained untouched and mostly neglected by lepidopterists, so that a rearrangement and comparison of the types had become highly necessary, which useful work has been undertaken and very ably carried out by Colonel Swinhoe. All the types have been brought to the British Museum, their synonymy carefully worked out and the species placed in their proper families and genera, many of them being figured in the eight coloured plates, and it is to be hoped the other parts will soon follow, and also that a list of the types which should be in the Museum and are missing will be added. There is one statement in the preface which requires correction, the only types of Walker's species described in his Catalogue which are in the Oxford Museum are those which

are expressly stated to be in "Coll. Saunders," all the others are in the British Museum, including those for which a locality is given before the list of British Museum specimens.

*Charles Darwin. His Life Told in an Autobiographical Chapter and in a Selected Series of his published Letters.* Edited by his son, Francis Darwin. (London: John Murray, 1892.)

PROF. DARWIN describes this volume as practically an abbreviation of the well-known "Life and Letters." The task of compression has been accomplished admirably, and there can be little doubt that the work will be cordially appreciated by a large number of readers. Of course it has been necessary to omit many details which are of interest to men of science, but everything is included which is really essential to a proper comprehension of Darwin's fine personal character, and a sufficiently full and clear idea is given even of his scientific labours. No one will read this fascinating book without feeling anew how much reason England has to rank Darwin among the greatest and noblest of her sons. The volume is enriched with a reproduction of an exquisite photograph of Darwin by the late Mrs. Cameron.

*Strange Survivals. Some Chapters in the History of Man.* By S. Baring-Gould. (London: Methuen and Co., 1892.)

EVERY one who has given any attention to anthropology is aware that many remarkable customs and beliefs, which are still to be found among the uneducated classes even in highly civilized communities are relics of ancient superstitions. In the present volume Mr. Baring-Gould examines various groups of these curious survivals, and traces them back to their origin in the ideas of past ages. He knows his subject well, and, being interested in it himself, is able to present it in a way which is likely to make it interesting to others. The value of the text is considerably increased by some well-selected illustrations.

#### LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

#### Botanical Nomenclature

IN NATURE for October 6 (p. 549) there is a note "on the progress of the negotiations concerning the nomenclature of genera, started by a committee of botanists at Berlin to supplement the decisions of the International Botanical Congress held at Paris in 1867." It is stated that "the botanical authorities of the British Museum favour the suggestions, those at Kew are against them."

Now this requires a little correction. It may be remarked to begin with that many botanists are exercised at the present time not merely about the nomenclature of genera, but also about that of species. Kew has, however, never given its adhesion to the attempts that have been made to bring about an international agreement on these matters. It has always felt that so many considerations must determine the course taken by the systematist in any particular case, that there is no advantage, but positive inconvenience, in being subjected to a hard and fast rule. It is therefore with no disrespect to, or want of sympathy with, the able school of Berlin botanists, who have recently formulated some new proposals with regard to nomenclature, that Kew has officially refrained from expressing any opinion upon those proposals. It has neither expressed approval nor disapproval.

In America Harvard has long occupied the leading place in the botanical world, and the principles adopted there have been substantially in accord with those adopted at Kew. Hitherto,

therefore, the leading English-speaking botanists who have occupied themselves with systematic botany have been in substantial agreement that the adoption of a strict law of priority in nomenclature must give way to considerations of convenience.

Well known and accepted names are not therefore to be lightly changed as the result of mere bibliographical research. As to specific names the often merely mechanical process of describing a new species is held to be of little value compared with the more difficult task of assigning to the plant described its true affinities and correct systematic position. The principle which guides Kew practice in this matter is laid down by Sir Joseph Hooker in the preface to "The Flora of British India" (p. vii). He remarks—

"The number of species described by authors who cannot determine their affinities increases annually, and I regard the naturalist who puts a described plant into its proper position in regard to its allies as rendering a greater service to science than its describer when he either puts it into a wrong place or throws it into any of those chaotic heaps miscalled genera with which systematic works still abound."

The following paper on the subject deserves the wider circulation which its reprint in NATURE would give it. It represents the Harvard tradition and practice, and is the last scientific utterance of Dr. Sereno Watson, who so soon followed to the grave his illustrious predecessor, Asa Gray.

Kew, November 14. W. T. THISELTON DYER

#### ON NOMENCLATURE<sup>1</sup>

(It was the request of the late Dr. Sereno Watson that the following communication, dictated by him in his last illness, should appear at an early date in the *Botanical Gazette*.—Eds.)

FOR some time I have had a desire to give expression to my views upon botanical nomenclature. Under the circumstances, I must speak briefly and somewhat dogmatically. In my opinion botany is the science of plants and not the science of names. Nomenclature is only one of those tools which is necessary to botany, and this being the case, points of nomenclature should be subordinated to science.

A principle of botanical convenience has been established by those who prefer one name to another on account of expediency or convenience. This principle should have a great deal of influence. It has been so recognized by the greatest botanists, and from their authority receives great weight. I prefer the word *expediency* as a better term than convenience to designate the principle, that the demands of science over-ride any merely technical claims of priority, &c.

Priority of specific names appears to be based entirely upon one section of the code of 1867. That simply says that when a species is transferred from one genus to another, the specific name is maintained. This principle is usually understood and applied in the way that the oldest specific name has a right in all cases to be retained. It cannot fairly be so interpreted and applied, since it governs only to the extent that this should be the law, but it is not to be made an *ex post facto* law. Thus when a transfer has been made, that ends the matter so far as the choice of a specific name is concerned, and no one is authorized to take up a different name. This practice of retaining the oldest name *under the genus*, no matter what older specific names there may be, was adopted by Dr. Gray in his later years and by the Kew botanists, for the reason that once established and pretty generally recognized, it would avoid the great mass of synonymy, which is being heaped like an Incubus upon the science. I must express surprise that Dr. Britton had not considered it his duty to publish the last written words of Dr. Gray which were addressed to him upon this subject and which expressed his positive opinions upon this point.

There is nothing whatever of an ethical character inherent in a name through any priority of publication or position which should render it morally obligatory upon any one to accept one name rather than another, otherwise it would be applicable or true as well in the case of ordinal names, morphological names, teratological, and every other form of name, to which now no one feels himself bound to apply the law of priority. The application of this law as at present practiced by many botanists, which would make it the one great law of botanical nomenclature, before which every other

must yield regardless even of common sense, is a mere form of fetishism exemplified in science. Many instances of the application of this law are not science but are rather superstition.

#### The Reflector with the Projection Microscope

THE lantern is now used for so many purposes—scientific, photographic, and recreative—that any improvement in its construction will be acceptable. When we look into this instrument whilst at work we must be disappointed at the large quantity of light lost by reflection and by dispersion—light which ought to go to the illumination of the screen. In the ordinary form of the lantern three lenses of dense glass are employed as condensers. Each of these six surfaces reflects and scatters the light, and the glass itself is absorbent of its rays.

The dioptric construction of the projection lantern has been well worked out by Messrs. Wright, Newton, Salomons, and others, but the catoptric principle, which would eliminate almost entirely these disadvantages, has been scarcely at all studied.

Although my experiments have been made solely with the limelight in various forms, the following remarks may equally apply to light given by the electric arc:—

If a reflector be used instead of the ordinary condensers it is obvious that the position of the lime cylinder must be reversed. This will present no difficulty, for the tube holding the jet can be bent into a helical form. The dark image of the lime-cylinder also will have no more practical disadvantage than is experienced by a like image formed by the small plane speculum of the Newtonian telescope.

As to the mirror itself, although a parabolic form is the most correct, a spherical surface will be sufficient for mere illuminating purposes, and thus expense may be spared in the grinding of the more difficult curve. A speculum of from 5 to 7 inches diameter, having a radial curvature of from 2½ to 3 inches, will grasp a large quantity of light, much more than that obtainable from the 5-inch condenser usually employed.

Silver deposited by one of the various reducing processes on the surface of a clear glass lens will have many advantages over a metal mirror. The front surface will give perhaps the finest definition, but by silvering the back part of a spherical glass film, or that of a ground lens, the brilliant surface will remain untarnished for an indefinite time, and the whitish bloom formed by slow volatilization of the incandescent lime is easily removed. This silver film adheres with remarkable tenacity, and it will bear a great deal of heat without blistering or becoming detached.

I have had considerable success in constructing such mirrors from the large ornamental glass spheres blown in Germany, and silvered within by Liebig's process, viz. with milk sugar and ammonio nitrate of silver. A glass sphere of 10 or 11 inches in diameter may be easily cut into eight or nine mirrors by a red-hot iron, and this without disturbing the silvering, which will require only gentle friction with a pad of cotton impregnated with a trifle of rouge to brighten it. Thus, at the cost of a few shillings, eight or more mirrors can be made, and also provision be made against possible accidents of cracking by heat.

The light radiant is so placed that the secondary focus is intercepted by a plano-concave lens of dense glass, as has been happily proposed by Mr. L. Wright. The convergent rays from the speculum are thus made into a parallel beam, which must be deprived of its heat by an alum-trough, for the light and heat at the substage condenser is very great.

Convergence, I find, is usefully promoted by a plano convex lens of about eight inches focus, placed two or three inches before the above-noted plano concave lens. In all other respects the arrangements are like those of the usual modern projection microscope.

I have pretty constantly used the ether-oxygen saturator, and I consider it to be perfectly safe, if ordinary precautions be taken. The oxygen, compressed in cylinders, is much recommended, as there can be no mixture of vapour, except at the right place. The U-shaped horizontal saturator, plugged with flannel, must be well charged with ether, or with the best gasoline, and care should be taken, before beginning or ending an exhibition, to shut off the oxygen tap before closing the ether

<sup>1</sup> From *Botanical Gazette*, vol. xvii.

tap. This will prevent the harmless "snap" from the mixture in the small chamber at the joining of the gas tubes. If a disc more than eight feet be required for the microscope, it will be well to use hydrogen gas instead of ether, since the calibre of the jet cannot in the ether light very well exceed  $\frac{1}{4}$  of an inch.

As an extra security, I pack the mixing chamber with asbestos fibre, moistened with glycerine, but, as before urged, the oxygen must leave the saturator, saturated.

To insure the coincidence of the foci of the reflector with the optical axis of the microscope, it will be well to place three adjusting screws in a triangle behind the mirror, and this last may have both a small vertical and horizontal movement.

I claim for this catoptric arrangement a larger grasp of light than can be got from ordinary lenses, and this may be effected also at a small outlay. For the amateur constructor the plan will afford many advantages. G. B. BUCKTON

#### Note on the Colours of the Alkali Metals

WHEN these metals are heated in a vacuum tube in such a way as to cause an extremely thin sublimate of the metal to condense upon the glass, the film so obtained will be found to possess a beautiful and strongly marked colour. That this colour is not in any way due to the combination of the metal with any lingering minute traces of oxygen, is evident from the fact that vacuum tubes which have contained the clean and bright metal for years, and in which the metal has been frequently melted and rolled about, and even vapourized in places, and in which, therefore, it is impossible to conceive of any oxygen remaining, will continue to show the phenomenon whenever a portion of the contained metal is heated. The experiment may readily be made by introducing a freshly cut fragment of the metal into a glass tube sealed at one end and drawn down to a narrow and thickened constriction near the middle. The tube is then drawn out at the open end and connected to a Sprengel pump. As soon as a good vacuum is obtained the tube is warmed throughout its entire length, the pump being still in operation, and the metal heated sufficiently high to cause it to melt and run out of the crust of oxide. When the exhaustion is again as complete as possible the tube is sealed off. The metal is once more melted, the whole tube being at the same time gently heated, and the molten mass allowed to filter through the constriction into the other portion of the tube. The vacuum condition of the tube allows of the metal freely running through an extremely fine aperture, and in this way it becomes perfectly separated from all dross. The tube is then sealed off at the constriction. On gently heating a minute fragment of the bright metal so obtained, by means of a small pointed gas flame, the coloured film of sublimed metal will at once be seen. Viewed by transmitted light, the colour of the film of sodium thus obtained is greenish-blue, inclining to green. Potassium gives a sublimate which is of a magnificent rich purple colour, while rubidium, on the other hand, forms a film which is a pure indigo blue.

In the cases of sodium and potassium, the colour of the metallic sublimates is different from the colour of the vapour as seen when the metals are boiled in an atmosphere of hydrogen. Potassium, it will be remembered, yields under these circumstances a vapour possessing an emerald-green colour, while that of sodium, which appears colourless when seen in small layers, shows a violet or purple colour when viewed through a sufficient thickness.

When the liquid alloy of sodium and potassium is treated in the same way, the sublimate obtained is found to be greenish in colour nearest to the source of heat, quickly shading off to blue and purple as it is more remote from that point, indicating apparently that the two metals sublime separately.

As a means of observing these colour phenomena, this alloy is more advantageously employed than the solid metals themselves, for, by rolling the liquid about, the sublimate may be wiped away and the experiment repeated indefinitely in the same tube.

As to whether the colours of these sublimed films are properties intrinsic to the particular metals, or are merely a function of the physical condition of the substances, it is perhaps rash to dogmatize. A number of other elements have been treated in a similar manner, but without similar results; thus lithium, cadmium, mercury, arsenic, tellurium, and selenium, when heated in vacuum tubes are readily sublimed, but in no case does the film appear coloured. On the other hand, however, it is well known that some of the very malleable metals when beaten out into thin films are capable of transmitting light varying in colour from green to violet. G. S. NEWTH

NO. 1203, VOL. 47]

#### Women and Musical Instruments.

IN answer to Prof. O. T. Mason's letter which appeared in a recent number of NATURE (vol. xlv. p. 561), I may draw attention to the following facts which bear upon a part of the subject which he broaches, namely, the part played by savage women in the use of musical instruments. In the South Pacific the "nose-flute" is very generally, though by no means exclusively, played upon by women. In the account of the voyage of Captain Cook and King there is in one of the plates a figure of a woman of the Tonga Islands seated under a hut playing upon a "nose-flute." A similar figure of a woman playing upon a "nose flute" may be seen in plate 28 of Labillardiere's "Voyage de la *Peiouse*," in the representation of a Tongan double canoe. Melville ("Four Months' Residence in the Marquesas Islands," p. 251) mentions playing upon the "nose-flute" as being "a favourite recreation with the females." In Wilkes' "U. S. Exploring Expedition," iii. p. 190, there is a description of this instrument as used in the Fiji Islands, and it is stated that "no other instrument but the flute ['nose flute'] is played by the women as an accompaniment to the voice."

Turning now to another genus of primitive instruments, viz., the "musical bow," we find a peculiar local form, the "Pangolo," occurring at Blanche Bay, New Britain. There are specimens of this at Berlin and Vienna. This instrument is stated by Dr. O. Finsch (*Ann. des K. K. Naturhist. Hofmuseums*, suppl. vol. iii. pt. 1, p. 111) to be only played upon by women of Blanche Bay. Guppy too ("Solomon Islands," p. 142), says that the women of Treasury Island produce a soft kind of music by playing, somewhat after the fashion of a jew's-harp, on a lightly-made fine stringed bow about 15 inches long.

It cannot, I believe, be said that any of these instruments have been *invented* by women, and it is undoubted that women in savagery but seldom figure as performers upon musical instruments. It would certainly be interesting to collect all the instances recorded. I hope that the above few notes regarding instruments in the South Pacific may be of use to Prof. Mason, and I can only regret that lack of the necessary time prevents my going further into the matter.

University Museum, Oxford,

HENRY BALFOUR

November 7

#### AN ANCIENT GLACIAL EPOCH IN AUSTRALIA

A VERY interesting "special report" has just been issued by the Department of Mines of Victoria, giving an account of the remarkable evidences of glaciation observed at a locality about twenty miles south-east of Sandhurst, and about the same distance north of the great Dividing Range.<sup>1</sup> The report is illustrated by a map and sections on a large scale, and by eight excellent photographic prints, showing the character of the deposit on the surface and in railway cuttings, the striated bed rock, and the striated and grooved blocks and boulders, so that full materials are given for the conclusion that we have here an undoubted glacial deposit. A brief summary of this report will therefore be interesting to all students of the phenomena and problems of terrestrial glaciation.

The district now specially described is about fifteen miles in one direction by five in another, and over this area of about thirty-six square miles the conglomerate is continuous, overlying the Silurian rocks of the district. It has generally a rounded or undulating surface, but shows cliffs about 100 feet high in some of the gullies, and its maximum thickness is estimated at 300 or 400 feet, while its highest point is about 700 feet above sea-level. As well seen in the cliffs and several railway cuttings, the conglomerate consists of a matrix of sand and clayey matter containing huge boulders, great angular and sub-angular masses of rock, pebbles, and rock-fragments of endless variety of size, form, and material. Many of these masses are planed, scored, striated, or polished.

<sup>1</sup> "Notes on the Glacial Conglomerate Wild Duck Creek." By E. J. Dunn, F.G.S. (R. S. Brain, Government Printer, Melbourne, 1892.)

Planing is very common, and is either flat or with a hollow or a convex surface. Some of the intensely hard hornfels blocks have been ground on one or more sides, several planes being sometimes ground on the same stone, while some very hard rocks are deeply grooved. In other cases the striations and scratches are so fine as only to be seen with a lens, while one surface block of very hard material has been ground down and polished, so that it glitters in the sun. In fact, every form of surface grinding produced by recent glaciation appears to be here present.

The surface of the ground is everywhere strewn with pebbles and boulders, the result of the washing away of the finer materials of the conglomerate, but, besides these, there is a tract of about two and a half miles by one mile near the centre of the conglomerate-area, on the north side of Mount Ida Creek, which is rather thickly strewn with large blocks, termed by the writer "erratics," though they can hardly be erratics in the sense of having been deposited on the present surface by ice. There are forty-five of these blocks, which are either of granite, sandstone, or quartz, and vary in size from 6 feet by 4 feet, to 20 by 12 feet. One of the finest, termed "The Stranger," of coarse-grained granite, is 16½ feet by 10½ feet, and 5 feet thick, the estimated weight being 30 tons. It is planed and scored in a remarkable manner as are most of the other blocks. It is curious that beyond this limited area only three or four large blocks are found on the surface, while no pebbles or boulders derived from the conglomerate are found more than a hundred yards beyond the present limits of that formation.

A striking feature of the conglomerate is the great variety of rocks present in it, seeming as if "the débris of a continent" had been here gathered together. There are an almost infinite variety of granites, syenites, gneisses, schists, quartzites, sandstones (hard and soft, coarse and fine), slates, shales, conglomerates, amygdaloids, porphyries, vein quartz, red, yellow, and grey jaspers, and many others. Some of these can be identified with existing rocks, but others are not known in Victoria. In some cases there is what appears to be river shingle, in others the delicate scratches preserved even on soft shale show that the material has not been exposed to any denuding action. There are also sandstone beds of considerable extent and thickness intercalated with the conglomerate, indicating that there were alternating periods of river or current action while the conglomerate was being formed.

The whole of the phenomena here briefly sketched point unmistakably to glacial action, in fact, there seems to be hardly any part of Wales or Scotland where such action is more clearly indicated. There are, it is true, no moraines, because the period when the conglomerate was laid down is too remote, both newer and older pliocene rocks overlying it in some places. Indeed, from fossils found in shales overlying what appears to be a similar conglomerate at Bacchus Marsh, south of the Dividing Range, the writer of the report is inclined to consider the whole formation to be of Palæozoic age. In one part of the area the bed rock is exposed, and this is covered with abundant striations crossing the stratification lines, indicating either powerful glacier or iceberg action.

A list of localities where similar conglomerates have been found is given, showing that they occur to the northward for about 250 miles along the foot of the hills bordering the Murray valley, disappearing under the Tertiary deposits of the lowlands; they have also been met with forming the floor of the auriferous deposits in mines at Creswick and Carisbrook, on the northern slopes of the Dividing Range, and also, as already stated, at Bacchus Marsh, and a few other localities on the south side of the range. We are not told, however, whether similar indications of glacial action occur in these localities. If these deposits are really all glacial and

contemporaneous, they indicate an extent of glaciated country that would imply either a very lofty mountain range or the occurrence of a real glacial epoch in the southern hemisphere.

The direct evidence of the superposition of Tertiary rocks of Pliocene age shows that the glacial conglomerate itself is of great antiquity, but no special attention appears to have been given to the question of the age of the so-called "erratics." The fact that they are found in so limited an area seems to show that they are not derived from the conglomerate itself by the process of sub-aerial denudation, and the same thing is indicated by the apparent fact that they all rest upon the present land surface. The photographs seem to indicate this, and nothing is said about their relations to the subjacent conglomerate, or whether any considerable proportion of them still form part of it, merely protruding above the surface, as would certainly be the case if they owe their present position to the mere washing away of the finer parts of the deposit. But, if so, why should they be called "erratics," as distinguished from the blocks and boulders which are still embedded in the formation? If, on the other hand, they are supposed to be true erratics—that is, to have been deposited on the present land-surface by ice agency—they must clearly be much less ancient than the conglomerate itself, or they would hardly retain such fresh-looking striations, grooving, and polishing as some of them exhibit. It is to be hoped that these most interesting deposits will be the subject of very careful study by Australian geologists, since they seem calculated to throw much light on the geological history of the old Australian continent.

ALFRED R. WALLACE

#### ON THE WALKING OF ARTHROPODA

IN a letter to NATURE, published January 8, 1891, I described the manner of walking of several insects. Recently I have been able to examine a greater number of Hexapoda, together with several Arachnida and Centipedes, and a few Crustacea. The results of most of these observations were communicated to the Royal Dublin Society a few weeks ago.

I stated in my former letter that most usually the insects examined moved three legs, *eg.* the 1st and 3rd on one side, and the 2nd on the other, almost, but not quite, simultaneously. In some insects it is the most anterior leg of this tripod which is raised first, in others it is the most posterior. An example of the first case is the cockroach, and of the second the blow-fly. But again exceptions appear to occur in each case. This almost simultaneous raising of the "diagonals" is shown by observations, photographic and otherwise, to be the rule in all the adult Hexapoda which I have examined, except the Thysanura. Of this last group I have observed *Tamocerus longicornus*, and find that, while it often moves by the simultaneous use of the diagonals, it also often raises its opposite legs simultaneously in pairs, especially when the animal is walking on a smooth surface, and using the sucker which is placed on the anterior part of the abdomen.

This use of the opposite legs in pairs was also found very frequently, as well as the diagonal walk, in the larva of one of the Coleoptera, and is always to be observed in caterpillars. Thus it is interesting to find that in one species at least of the Thysanura, which are regarded as having preserved many of the characteristics of primitive insects, the adult walks in the same manner as the larvæ of other insects.

It is to be observed that those insects which have long antennæ move them, and apparently the maxillary palps, in accordance with the diagonal rule, for when the front leg of one side is moved the antenna of that side is twitched.

A midge and some arachnids very frequently use the front pair of walking legs as antennæ. The midge which I observed probably belonged to the Cheironomidæ, it often, when at rest, stood on the two posterior pairs of legs with the anterior pair aloft in the air, when walking it moved them much as a beetle moves its antennæ, gently tapping the ground in front of it with them, their motions being always subject to the diagonal rule, in flight the midges often hold the anterior pair of legs straight out in front, while the last pair are held out in a similar manner behind, and probably have the effect of balancing the insect.

The spiders photographed (*Tegenaria Derhami* and *Tarantula pulverulenta*) also exhibited the diagonal motion and sometimes the use of the anterior pair of legs as antennæ. When, in order to photograph them, these animals were put on a piece of paper floating in a shallow dish of water, so as to confine them without casting a shadow on the space in which they walked, they used frequently to stand on the three posterior pairs of legs at the edge of the paper, while they moved their anterior pair of legs through the air, or touched the water lightly with them. Several spiders—for instance, *Theridion Sisyphum*—have the anterior pair of legs longer than the others, and very frequently seem to use them as tactile organs. Specialization in this direction is carried very far in the Pedipalpi, in which group the anterior pair of legs are very long, thin, and flagelliform.

The wave of motion in one set of diagonals (*i.e.* the 1st and 3rd of one side, and the 2nd and 4th of the other) in the Tarantula sometimes travelled from before backwards and sometimes in the opposite direction, while in *Tegenaria* it passed on the whole forwards, but sometimes commenced by the raising of one of the middle legs, or by the raising of the two extreme legs of a set.

When confined on the floating island of paper, the Tarantula sometimes, after a good deal of hesitation, took to the water. When on the surface of the water, its legs, and sometimes the under surface of its abdomen, made conical capillary depressions in the surface, so that the water acted as a diffusing lens to the sunlight, and a dark circular shadow surrounded with a bright line appeared on the bottom of the dish corresponding to the depression at the tip of each leg. This suggested a method of determining the weight supported by each leg, for the diameter of the depressions, and consequently that of the shadows, bears some ratio to the weight on the point which causes the depressions. By fixing the leg of a spider on the end of a straw, hung delicately as a balance-beam, and by measuring the diameters of the shadows caused by the depressions in the surface of the water formed by this leg for various positions of a rider on the straw, I find that these diameters are approximately proportional to the weight on the point causing the depressions. Thus, by dividing the total weight of the spider proportionally to the diameters of the shadows, we get approximately the weight on each leg.

Fig 1 is from a photograph of the Tarantula standing

FIG 1

on water; above the spider in the picture is its shadow on the bottom of the vessel, and at the ends of the three posterior pairs of legs in the shadow appear circular shadows corresponding to the depressions made by the legs; and there is also a shadow thrown by the depression caused by the abdomen. The weight of this spider was 30 mgrs. Thus we find that approximately the

weights on the legs are the following.—On the right side, 2nd supports 1 875 mgrs, 3rd, 7 125 mgrs, 4th, 3 375. On the left side, 2nd, 4 875 mgrs, 3rd, 5 250, 4th, 3 000, and the abdomen supports 4 500 mgrs. When walking, the Tarantula usually supported all its weight on a tripod formed by the 2nd and 4th legs on one side, together with the 3rd leg on the other side. The weights on the tips of the legs when one photograph was taken were found to be.—On the 2nd right leg, 9 50 mgrs, on the 4th right, 10 25, and on the 3rd left, 10 25.

Profile photographs also seem to show that the 1st pair of legs are not generally used to support much weight. Fig 2 is a diagram of the positions of the 1st pair of legs

FIG 2

drawn from a number of profile photographs of *Tegenaria*. The first position, *a*, is that of the leg which has been thrown forward, and is just about to come to the ground, *d* shows the position of the 1st leg when the body has come forward, owing probably to the traction of this leg as well as to the pushing of some of the other legs, and so the leg is bent, *b* and *c* are intermediate positions. The next

FIG 3

figure is a somewhat similar diagram of the 4th pair of legs made from profile photographs. At *a* the leg has just been moved forward, and is on the ground, and is in a good position both for bearing the weight of the body and shoving it forward. At *e* it is stretched to its full length, and so is not of any use in driving the spider forwards, while, owing to its almost horizontal position, it is almost useless in supporting the weight of the body. Accordingly the spider has commenced to raise the extremity of the leg prior to lifting the leg completely off the ground.

Last autumn I had the opportunity of observing two scorpions which Mr. R. J. Moss brought from North Africa and exhibited at the Royal Dublin Society. These also appear to proceed according to the diagonal rule; but I do not know what is the order of succession in one set of diagonals, as I have not yet photographed any of these animals.

The hermit crab uses three pairs of legs in walking—the chelæ, and two pairs of thoracic walking legs, these it uses according to the diagonal rule, whether it walks sideways or forwards. Sometimes it simply shoves the chelæ along the ground without lifting them, while it moves the two pairs of legs in a diagonal manner. One of the Asellidae I found often used the opposite legs in pairs simultaneously when walking.

The centipede does not either raise its opposite legs in pairs together, nor does it move its legs according to the diagonal rule. In a number of photographs taken with an exposure of about the 1/10th of a second the legs appear to move in threes diagonally, for instance, the 3rd, 4th, and 5th, and the 9th, 10th, and 11th on one side move simultaneously with the 6th, 7th, and 8th of the other side, while on the first side mentioned the 6th, 7th, and 8th, with the 12th, 13th, and 14th are on the ground, and on the other side the 3rd, 4th, and 5th, and 9th, 10th, and 11th are also on the ground. At either end of the body this order is usually more or less disturbed, thus on the right side the 14th leg might be on the ground, while on the left the 13th, 14th, and 15th would be also in contact with the ground; but

in none of the photographs was the symmetrical diagonal movement of the successive threes disturbed between the 2nd and 12th pairs of legs inclusive. This apparently simultaneous motion of three adjoining legs may probably be explained by supposing a series of waves, whose crests traverse three legs in the  $\frac{1}{70}$ th of a second, to be passing along the body, since the different photographs show different legs moving in threes, thus in one photograph the 6th, 7th, and 8th on the left side are seen to be moving forward, while in another the 5th, 6th, and 7th, are moving.

Since reading the paper at the Royal Dublin Society, Mr. G. H. Carpenter brought to my notice two papers by M. Jean Demoor, "*Recherches sur la Marche des Insectes et des Arachnides*" (*Archives de Biologie*, 1890) and "*Recherches sur la Marche des Crustacés*" (*Archives de Zoologie Expérimentale et Générale*, 1891). M. Demoor points out the simultaneous use of the tripod in the insects which he examined, but as he did not use photography he does not seem to have observed the minute want of synchronism of the legs of a tripod. Figs 4 and 5 illustrate this<sup>1</sup>. These are two photographs taken of the same specimen of *Blapt mucronata*. Fig 4 is from a photo-

FIG. 4

graph taken with a long exposure, and shows the 1st and 3rd of the left side, and the 2nd of the right moving at the same time, just as it appears to the eye. Fig 5 is from

FIG. 5

a photograph taken with less than half the exposure of 4, and shows that while the 1st leg on the right side is raised off the ground, the 3rd on the same side and the 2nd on the left have not yet been raised. That they have not been raised and are now come to rest is shown by their backward position with regard to the body and other legs. These two photographs also show that the antenna is often twitched almost simultaneously with the motion of the 1st leg of its side. M. Demoor also observed a scorpion (*Buthus australis*), but its method of progression does not seem to have agreed with that of the scorpions (*Buthus europæus*) which I observed. He has not, so far as I know, recorded any observations on spiders.

HENRY H. DIXON

Trinity College, Dublin, June.

#### ON IRON ALLOYS

THE merely mechanical expert in the working of metals would naturally consider it probable that a given metal when fused with another would communicate its physical properties, roughly, in proportion to the quantity added. A soft, tough metal added to iron would, from his point of view, render the latter softer, a brittle or hard metal would have the contrary effect, and so on throughout the whole series of metallic alloys.

<sup>1</sup> Figs 4 and 5 show the legs, which are raised from the ground, quite sharp. In the negative they are more or less blurred owing to their motion during the exposure.

Actual experiment would soon, however, show the fallacy of this, and that in the majority of cases no reliance could be placed on this assumption solely based on the physical properties of the elements severally considered. A further study of the laws which govern chemical combination would quickly show that alloys formed by fusion were not merely intermixtures, but that something else took place, bodies being often produced, or rather formed, differing considerably from the metals severally used. It would therefore be fair to assume that the metals entered into combination with each other, and yet it would be found that the problem even at this stage was not completely solved.

Further inquiry and experiment would indicate that it was not always possible to prove that chemical combinations "were in all instances" formed by fusion alone. Instead of this something closely akin to only an intermixture of the metals occurred; second, one of the metals had apparently dissolved in the other; third, it was difficult to differentiate between intermixture and solution. Here we are on all fours with modern ideas which seem to have met with general acceptance, although it is not denied that elements or metals are capable of chemically combining with each other. We are not, however, quite prepared to draw a hard and fast line between chemical combination of the metals with each other, solutions, and intermixtures of metals. One appears to merge into the other, and no good reason "so far as is known" can be given why solution, as ordinarily understood, or as defined by Van 't Hoff and others, may not be as applicable to fused metals as to the solution of certain salts in water.

Water at 60° is nothing more nor less than fused ice, fused iron, therefore, may obey the same laws, and, "like water," may be capable of dissolving certain substances, and rejecting others, temperature constituting the sole difference—or plainly, solid ice is fusible at 60°, iron at about 2500°.

Now what happens in the case of water? Certain bodies are soluble in it, others not, on lowering the temperature, these bodies are to a certain extent rejected, and nearly, but not quite, pure ice is formed, and so far as we know this equally applies to fused iron. As an instance, on cooling, the carbon is rejected, and appears in the graphitic<sup>1</sup> form, merely diffused throughout the solid cold metal. It is impossible here to treat this matter in detail; but enough, we think, has been said to indicate that the analogy is fairly complete throughout.

But there is another matter—apart from the solution of foreign bodies in fused ice or iron—which requires to be discussed. Ice dissolves in warm water, and so does cold iron or steel in superheated fused iron, the hot fluid metal from the Bessemer converter fuses or dissolves large lumps of solid steel placed in it as easily as ice is thawed in warm water. Temperature here, in both instances, determines the quantity which can be added, the higher the heat, the greater the quantity which can thus be dissolved or fused, ere the bath becomes thick, pasty, and incapable of being poured out into another vessel.

In so-called solutions the same rule appears to hold good, but, as all chemists know, there are many exceptions; in some cases heat is evolved, in others absorbed, and some bodies are more soluble in the cold fluid solvent.

It is, however, believed that no instance can be quoted of a body being more soluble in iron at a low degree of heat than at a high one. Confining ourselves to hot fluid iron or steel, it apparently readily dissolves cold metal. Similarly, other bodies, such as copper, &c., are dissolved in the same way when added to it.

The cold metal is fused by absorption of the enormous

<sup>1</sup> The relations existing between carbon and iron are peculiar, and require to be separately discussed.

extra heat of the bath, but this may not be strictly true, for something like solution may also take place. In melting iron in the reverberatory furnace it often happens, when the heat is insufficient, that the iron sets in a pasty semi-fluid mass on the bottom of the furnace, the operator then adds some molten iron, and the whole soon becomes fluid.

This process is closely akin to solution. It cannot be explained as simple fusion of iron in iron, the molten iron, in fact, seems to exert a solvent action on the pasty metal, and heat alone plays only a secondary part. This may seem absurd to those not practically engaged in the manufacture of iron, but the fact remains as the result of the experience of iron-workers.

It follows that other metals can be similarly taken up, and the theory of certain iron alloys simplified. There are certain metals intimately related to iron on the periodical scale of the elements, also by atomic volume and atomic weight, and their combination with iron may be achieved by fusion, and possibly something like solution as well, as described, resulting in the production of a similar homogeneous product, which compound metal cannot well be termed either a solidified solution of one metal into another, a chemical combination, or intermixture of metals. The physical properties of this alloy, of course, are different from those of iron. This seems an extreme view to take, but it may be mentioned that the absolutely pure elements prepared by special experts are known in some instances to differ somewhat from those accepted as such in an ordinary laboratory. It has been also noted that the so-called impurity extracted does not differ very greatly from the pure product, and yet is not precisely the same—(quoting from memory, "this applies especially to alumina," why not iron?)

As the result of an extensive experience in the chemical examination of crude iron, steel, and the purest wrought iron, one finds that some metals cling persistently to iron—manganese is always present, nearly all contain copper, nickel also may often be detected if sought for, chromium is not so rare a constituent as might be supposed—all, however, in minute quantities in the case of wrought iron or Bessemer decarbonized metal.

It is curious that these particular metals should cling to iron, but the previous exposition of their relation to iron possibly affords a clue accounting for their persistent presence.

Again, one gathers from a study of Crookes's theory of the genesis of the elements, together with his spectroscopic researches on the composition of the rare earths, yttria, &c., that one so-called element apparently merges into another by almost insensible gradations, it is probable that iron is one of these. Probably it is, for recently it has been all but demonstrated by Prof. Roberts-Austen and others that iron is a compound body, but the relations betwixt these bodies are so close that they have not been isolated, and both are still termed iron.

We have evidence of the possibility of one element merging into another and that iron is not an element, and any one who has studied the periodic law cannot fail to see at least the probability that minute variations in the composition of the elementary bodies may occur, which, however, cannot well be differentiated by our present comparatively coarse analytical methods. Modern methods, however, have been sufficiently accurate to enable us to show that certain relations can be traced throughout the whole series of the elements, and it is in this way that the periodic law has been formulated; and fairly trustworthy atomic weights have been obtained.

Admitting the possibility of minute variations in the composition of elementary bodies, or more correctly that, as urged by Crookes, an element may have more than one atomic weight—the atomic weight accepted being the mean of these: with the periodic law for our guidance, and also attaching due weight to the relations existing

betwixt the weights and volume of the atoms, it would seem that the theory advanced of the homogeneous formation of bodies by fusion is in accord with the periodic law, &c., governing the genesis of the elements.

This is equivalent to saying that a fourth state of combination may be imagined, which is—

- (1) Neither solution of one metal in another
- (2) Chemical combination of bodies
- (3) Intermixture of bodies

Hadfield's alloys of iron and manganese may be members of this class.

The first series of these alloys are hard, but when the manganese exceeds 7 per cent the metal softens and alloys containing about 12 to 15 per cent of Mn are strong, tough, cannot be annealed, and cannot be termed either iron or steel.

The same to a certain extent, it is believed, applies to the nickel alloys of iron.

There are other properties, which show that the FeMn alloys are unique.

The alloys of chromium and iron recently made by Mr. Hadfield appear to be of the same class, as also those of nickel and copper with iron.

More plainly, the homogeneous compound bodies previously commented upon may be practically termed elementary bodies similar to the quasi-elements of the rare earths studied by Prof. Crookes. These being, however, within the domain of practical chemistry, it is easy to demonstrate their compound nature, not forgetting "that, as previously noted," it is not easy to entirely eliminate these bodies allied to iron.

We may even go further and assume that the fourth state indicates a species of combination even more intimate than the chemical combination of the chemists.

In fact, reactions "occur quite unlike chemical combination in which atoms only combine with atoms, or bodies are built up atomically." The fourth state may go beyond this, at present this is pure assumption, yet an eminent man of science has suggested that even the atoms may be *smashed*, and this is equivalent to saying that under certain conditions the atom may be non-existent, or in an alloy of, say, iron and nickel or iron and manganese, the separate atoms of iron and manganese do not exist, or in an alloy of iron and Mn or nickel, the severally separate atoms of Fe and Mn, &c., may have no tangible existence apart from each other, as in the case of true chemical combination. Further, this seems more probable if we remember that chemical combinations are, according to modern views, nothing more nor less than structural formations governed by physical laws which regulate their molecular arrangement and the relative positions of the atoms to each other, just as in any structural work built by the hand of man, certain laws or rules must be adhered to. In Nature's laboratory something beyond this may be going on—something, indeed, altogether outside our limited knowledge and experience.

Iron is only one member of a very complicated group, which are closely in accord both as regards their atomic volumes and weights and position on the periodic scale of the elements, and, if we are to accept the work of Prof. Crookes, the well-known investigations of Prof. Roberts-Austen, Osmond, and some data derived from the spectroscopic work of Lockyer, one may be really justified in assuming that quasi-elements may be formed by fusion in the workshop—*i.e.*, elements which can afterwards be dissociated by ordinary chemical processes. The accepted elements, it is true, have not been so dissociated; but it is clear something has been done to indicate the compound nature of at least some of these.

The theory of the possible existence of iron as a quasi-element when fused with other elements of like nature clashes with the generally received ideas of chemical

combinations or solution, because undoubtedly these are formed.

Granting that chemical combinations likewise take place, does it not seem probable that when these latter are present they may be strictly termed impurities?

If so, iron alloys may be divided into two classes—(1) those in the homogeneous or fourth state, "the true alloys," (2) those in which chemical combinations or solution only takes place, and this latter class may be termed impure metal, in contradistinction to the first or quasi elementary body.

In conclusion it is urged that many of our most eminent metallurgists and men of science have "by very different modes of investigation" come to the conclusion that iron itself is a compound very complex body. It is true that we have only indirect proof of this, but it only remains to find methods of isolating these bodies from each other.

### NOTES

THE medals of the Royal Society are this year awarded as follows—The Copley Medal to Prof Rudolph Virchow, For Mem R.S., for his investigations in Pathology, Pathological Anatomy, and Prehistoric Archaeology, the Rumford Medal to Mr Nils C Dunér, for his Spectroscopic Researches on Stars, a Royal Medal to Mr John Newport Langley, F R S., for his work on Secreting Glands, and on the Nervous System, a Royal Medal to Prof Charles Pritchard, F R S., for his work on Photometry and Stellar Parallax, the Davy Medal to Prof François Marie Raoult, for his researches on the Freezing Points of Solutions, and on the Vapour Pressures of Solutions, the Darwin Medal to Sir Joseph Dalton Hooker, F R S., on account of his important contributions to the progress of Systematic Botany, as evidenced by the "Genera Plantarum" and the "Flora Indica," but more especially on account of his intimate association with Mr. Darwin in the studies preliminary to the "Origin of Species." The award of the Royal Medals has been graciously approved by the Queen.

THE American Ornithologists' Union has been holding its tenth congress at Washington. The meetings began on Tuesday, and were held in the U S National Museum.

JAMES PLANT, F G S., of Leicester, who has just died in his seventy-fifth year, was well known as a local geologist in the midland counties, and as a member for some years of the Committee of the British Association on Erratic Blocks. Such blocks are numerous in Leicestershire, those on the southern side of the county being chiefly derived from the Charnwood range, and Mr. Plant was diligent in searching out and recording the more important of them. Several large boulders striated and partially polished stand in the grounds of the Leicester Museum, rescued by him from various railway cuttings. In 1868 he collected a very fine series of massive specimens representing all the hard rock formations of his native county, for exhibition at the meeting of the Royal Agricultural Society. These were afterwards built up into a great cone about 8 feet in diameter and 15 feet high in the museum grounds, and when the enlargement of the building necessitated its removal they were formed into a diagrammatic geological section on another site. Having to be again removed two years ago some of them were used to form a rough geological model of Charnwood Forest in the Abbey Park. In his latter years Mr. Plant acted as consulting geologist in several important borings for water and coal. The curious concentric rings on the face of a rock in Charnwood Forest interested him greatly, and with much trouble and labour he succeeded in obtaining plaster casts of them. He was active also in procuring photographs of many of the most remarkable geological features of the district.

DR R V WETTSTEIN, of Vienna, editor of the *Oesterreichische Botanische Zeitschrift*, has been appointed ordinary Professor of Botany at the University of Prague.

THE Prussian Government has decided to introduce the use of the Centigrade thermometer instead of that by Reaumur, which is still in use in some parts, and no further Reaumur thermometers are to be supplied to any public officials. The Centigrade thermometer has long been in use in Germany for scientific purposes.

A VALUABLE collection of fossils, minerals, and shells, comprising several thousand specimens, and particularly rich in specimens from the carboniferous formation, has just been presented to the University College of North Wales by Mr. Evan Roberts, of Manchester. It is hoped that this gift will become the nucleus of an important geological collection suited to the educational requirements of a University College, and that similar gifts will from time to time be made to the College by those interested in the progress of geological study.

THE Oxford Medical Society held its first meeting on Saturday last, at the University Museum. Sir Henry Acland presided. The inaugural address was delivered by Sir James Paget. He said they all knew that the practice and science of medicine, or, as it was sometimes called, the science and art of medicine, were by some regarded as things quite distinct, wide apart, and in study almost incompatible. A few there were who had the capacity of pursuing both. The great mass of those engaged in the pursuit of medicine were either practitioners or men devoting themselves to science. Each method of work was essential to the practice of the other. It might be asked how could practitioners work as men of science even where they had the time for it? He believed that would come about by the increase in the teaching of science in all medical schools and Universities. He pointed out the work which might be undertaken by the society, and spoke at length on various subjects which might be studied with advantage. Prof Burdon-Sanderson said the society had been established for the furtherance and promotion of science, and they wished to make an advance, so to speak, towards the University. There was a yearning in the minds of the medical profession in Oxford to unite itself more closely than it had hitherto with the scientific studies of the University which depended immediately on medicine.

THE weather has continued very unsettled during the past week, the most notable features being the prevalence of fog and abnormally high temperature. During the latter part of last week fog extended over nearly the whole of England, as well as a large part of the Continent. In London and the suburbs intense darkness occurred on several days, interspersed with very short intervals of sunshine, but in the north western parts of the kingdom the weather was generally fair. These conditions were due to the distribution of pressure, which was cyclonic over the western portion of these islands, but anti-cyclonic over western Europe. Temperature was uniformly high for the season, the daily maxima ranging from about 50° to 60°, and reached 62° in several places in the southern counties on Monday. This maximum is the highest that has been recorded in the neighbourhood of London during the last ten years. In the early part of the present week a deep depression passed to the westward of Ireland from the Atlantic, causing southerly gales in the north and west, with rain in all parts of the country, the amount measured at Valencia Observatory on Monday exceeding an inch. On Tuesday afternoon a fresh depression reached our south-west coasts from the south-eastwards, while a trough of low pressure lay over the Bay of Biscay and France, causing further heavy rains and local fogs. For the week ending the 12th instant the reports show that bright sunshine was, as might have been expected, very deficient generally, especially over northern and eastern England, where the percentage of possible duration was only 9; the lowest

amount was at Stonyhurst, where it was only 2 per cent. The south-west of England enjoyed the brightest weather, as there the sunshine amounted to 33 per cent. of the possible amount.

THE current number of the *Annalen der Hydrographie* contains a short note of a hurricane at Marseilles on October 1, which is said to have been more severe than any experienced during the last thirty years. From 8 a.m. until 1 p.m. the wind, rain, hail and lightning were incessant, all the lower parts of the town being under water, while several houses and bridges in the neighbourhood were destroyed. The weather charts for the day show that the storm was caused by a small whirl which occurred on the south-eastern side of a large depression, whose centre lay in the south of Scotland. While the centre of the depression scarcely altered its position, the whirl increased in extent, but diminished in intensity, and on October 3 it had crossed Northern Italy and lay over Hungary.

MR. CHARLES CARPMAEL, director of the meteorological service of the Dominion of Canada, urges in his latest report the need for more thorough inspection of the various stations under his control. He points out that the stations in Great Britain and Ireland, connected with the Meteorological Office, London, are constantly inspected, and that in every country where meteorology is worked out on a large scale inspection is admitted as the only system whereby trustworthy and satisfactory results can be obtained. He recommends therefore that a sufficient appropriation should be placed at his disposal to enable him to have the meteorological stations in the Dominion inspected and the observers thereof thoroughly instructed in the duties required of them. If this is not done the data furnished to the Central Office cannot, he says, be accurate.

TWO numbers have now been issued of the new series of the quarterly cryptogamic journal, *Grevillea*, under the editorship of Mr G. Massee. It is conducted very much on the old lines, and contains many articles of interest to cryptogamists. It is strange that one peculiarity of the journal should still be retained which detracts very much from its usefulness as a work of reference, the absence of any table of contents or index to each separate number.

THE Cambridge University Press has issued the Sedgwick prize essay for 1886, by the late Thomas Roberts, on the Jurassic rocks of the neighbourhood of Cambridge. The essay has been edited by Mr Henry Woods, Scholar of St John's College, and Lecturer on Palæontology in the Woodwardian Museum. In an interesting preface, Prof. T. McKenny Hughes explains the nature of the problem which the author endeavoured to solve, and expresses his belief that the work is indispensable for the student of Cambridge geology, and most valuable for all specialists in the Jurassic rocks.

SIR HENRY H. HOWORTH has completed and will shortly publish a considerable work on which he has been long engaged entitled, "The Glacial Nightmare and the Flood." It begins with an account of the various theories which have been forthcoming to explain the drift phenomena, in which the very large literature on the subject has been for the first time condensed and tabulated. It then proceeds to criticize the extreme glacial views which have recently prevailed among geologists, and to call in question the theory of uniformity as developed by the followers of Lyell and Ramsay, and especially to attack the notion that ice is capable of distributing materials over hundreds of miles of level country, and of producing many of the effects attributed to it by the glacial school of geologists. The author argues that the evidence points to the former existence of much larger glaciers than exist now, but not to an ice period when the temperate regions were covered with ice. On the contrary, these great glaciers entered side by side of fertile plains. Lastly he

argues that the phenomena of the drift can only be explained by reverting in a large measure to the diluvial theories of Sedgwick and Murchison, Von Buch and others, and that the purely geological evidence is completely at one with that collected in the author's previous work on "The Mammoth and the Flood," and establishes that a great diluvial catastrophe forms in the temperate zones the dividing line between the mammoth age and our own.

THE Libraries Committee of the Glasgow Town Council, in the eleventh general report on the Mitchell Library, Glasgow, make a suggestion which deserves to be kept in mind. It is to the effect that an admirable way of perpetuating the memory of a relative or friend would be to present a public library with a separate collection of books, to be kept together and called by such name as may seem proper to the donors. "Such a memorial collection," say the Committee, "would, with propriety, be composed of books devoted to any department of literature or learning in which the person to be commemorated was interested or which the donors desired to see more fully represented."

A VALUABLE paper on the present state of Morocco is contributed to the current number of the *Revue Scientifique*, by M. A. Le Châtelier. He brings out very strikingly the mixed character of the population of Morocco. First he notes the fair-haired, blue-eyed type, which is represented in the sculptures of some tombs of the twelfth Egyptian dynasty. Then come the various Berber types, the Arabs, several elements (including the Draoua) which have come down from remote antiquity, Spanish Moors and Jews, and the descendants of Christian captives. M. Le Châtelier thinks we must also take into account descendants of Phœnicians, Carthaginians, Romans, Byzantines, and Vandals.

MR C. H. EIGENMANN has contributed to the Proceedings of the U. S. National Museum (vol. xv) a paper in which he presents a valuable account of the observations made by him on the fishes of San Diego and vicinity from December 11, 1888, to March 4, 1890. Especial attention was paid to the spawning habits and seasons, the embryology, and migration of the fishes of Southern California. A diary was kept of the occurrence of each species throughout the year 1889 and part of 1890. Mr. Eigenmann's knowledge of the occurrence of each species is largely based on observations of the fish brought into the markets, which he visited twice or thrice daily, and of those caught with hook and line by the numerous habitual fishermen found on each of the wharves, and of those caught by the seiners, whom he accompanied on several occasions. During the early part of 1888 each individual fisherman sold his catch as best he could and the data for this part of the year are not as full as for the latter part of 1888, when practically the whole catch was brought to two markets, where Mr. Eigenmann could see the fish as they were unloaded. The knowledge of the ocean fishes is largely derived from frequent visits to ocean tide-pools, from the fish brought to the markets, and from a two weeks' stay on the Cortes Banks. As a matter of course, hundreds of specimens of most species have been observed to every one preserved, and the present paper is to be looked upon as a contribution to the economic history of the fishes, rather than to the anatomy of the various species. With two exceptions, the types of the new species discovered, and otherwise interesting specimens, have been deposited in the U. S. National Museum. A nearly complete series of types has been placed in the British Museum, and minor series in the Museum of Comparative Zoology and the California Academy of Sciences.

THE Committee of the Field Naturalists' Club of Victoria have hit upon an excellent plan for interesting the more active members in definite lines of investigation. They have arranged that special meetings shall be held once a month for the carrying on of practical work which cannot conveniently be undertaken

at the ordinary monthly meetings. The first of these special meetings assembled on August 22 in the Royal Society's Hall, Melbourne. We learn from the Club's journal that there was a good attendance of members, those interested in microscopic work being principally represented. No fewer than twenty-four microscopes were set up. Mr J. Shephard undertook to give a slight sketch of some interesting forms amongst the rotifera. A typical form was first described, the chief points in its structure being made clear by good diagrams, and then variations in the various orders from this type were briefly referred to—special allusion being made to the modifications in the ciliary wreath and the foot. Mr Shephard had fortunately met with a large number of the Australian member of the rhizotic group (*Lacunularia pedunculata*), and at the conclusion of his remarks a slide of mounted individuals was handed to each member for careful examination under the microscope. Half an hour was profitably spent in the endeavour to make out all the points of detail in the specimens, during which time Mr Shephard also supplied full information as to the best methods of mounting and examining these interesting organisms. Some four or five entomologists had a quiet corner to themselves, where they compared specimens and talked over some plans for future operations.

At the ordinary monthly meeting of the Field Naturalists' Club of Victoria, on September 12, the feather boots of a native rain-maker from M'Donnell Ranges were exhibited. It is believed among the natives of certain tribes in Central Australia that droughts are caused by the swallowing up of all moisture by a rain-devil. If this personage can be captured and made to disgorge, rain follows at once. The feather boots are worn by the native rain-maker in order that he may steal noiselessly and unawares on the author of the drought and consequent misery. Mr A. W. Howitt is having drawings made of these boots, which he considers to be one of the most valuable and interesting additions to aboriginal ethnology yet brought to light.

An interesting paper on the anthropology of Spain, contributed to the "Anales" of the "Soc. española de Historia Natural" by Luis de Hoyos Sáinz and Telesforo de Aranzadi, has now been published separately at Madrid. The paper is accompanied by three excellent maps, in which, by means of various degrees of shading, the authors bring together a number of most interesting conclusions. One of these maps shows the cranial types which prevail in different parts of Spain.

In the November number of the *Mediterranean Naturalist*, Mr John H. Cooke gives an interesting account of his recent discovery of *Ursus arctos* in the Malta Pleistocene. The late Admiral Spratt and the late Prof. Leith Adams found among the cavern deposits of the Maltese Islands a remarkable land fauna, including elephants, hippopotami, land tortoises, gigantic dormice, and aquatic birds. From the fact that many of the remains of elephants presented the appearance of having been fiercely gnawed, it was concluded that carnivores had lived in the district, but, notwithstanding the most diligent search extending over a period of twenty years, the only tangible evidences in support of the inference were these gnawed bones. Mr. Cooke has now solved the problem. His discovery was made in the spring of the present year, when, with the aid of a money grant from the Royal Society, he carried out some excavations in the Har Dalam cavern, a subterranean gallery situated in a gorge of the same name in the eastern extremity of Malta. After having excavated six large trenches and obtained some hundreds of bones of *Hippotamus pentlandi*, *Elephas mnadramensis*, *Cervus barbaricus*, and numerous other animals, he had the satisfaction of discovering an entire ramus of the lower jaw of a bear, *Ursus arctos* with its canine and molars in situ, as well as five other canines belonging to other individuals of the same species. Afterwards four other canines were dis-

covered, each of which was in a fairly perfect state of preservation. One of these Mr A. S. Woodward has determined as belonging to the left side of the mandible of a species of *Canis* equalling a wolf in size. Associated with these remains were found several vertebrae and fragments of limb-bones of hippo, and vertebrae and portions of horns of stags; but none of them presented any evidences of having been gnawed.

THERE is some difference of opinion as to whether the process of digestion is promoted or hindered by bodily exertion. Herr Rosenberg recently made some experiments on a small dog with reference to this point (*Pflüger's Archiv*). The animal was fed once daily with a certain quantity of lean horseflesh, lard, and rice, and the amount of nitrogen and fat daily absorbed was determined by an examination of the excreta. There were five series of experiments, each consisting of a rest period of several days, followed by a working period of several days, the dog being made to work in a kind of treadmill. In some cases these efforts were made during stomacheal digestion, in others during intestinal. In both series of experiments the differences observed lay within the limits of physiological variations, the inference being, accordingly, that in a healthy dog the utilization of food is quite independent of whether the animal rests during digestion or is energetically at work. Whether this applies to man could only be determined by direct experiment. Herr Rosenberg thinks it probable, however, as observations on people with heart disease appear to show that the absorption of food is to a certain extent independent of the circulation and distribution of the blood.

THE characteristic mantle of ascidians, consisting of a ground mass with cellulose and embedded cells, has been much studied, especially with regard to the origin of the cells. The most favoured view is that it is produced by the ectoderm, that it is a thickening of the outer epithelium. Recent researches by Kowalevsky, however (described to the St. Petersburg Academy) give reason for believing that the mantle-cells are from the mesoderm. Studying the metamorphosis of *Phallusia mamillata*, he observed certain mesoderm-cells applying themselves to the ectodermal epithelium, penetrating it and entering the mantle, which (secreted from the ectoderm) was before quite transparent. These cells also move freely about in the mantle, and this amoeboid movement is further in favour of their mesodermal nature. A similar process occurs in vertebrates, viz., the passage of lymph-cells (leucocytes) through epithelium to the surface of a mucous membrane, or the surface of the body (in fishes), the mucous layer is comparable to the ground mass of the mantle. But in vertebrates the cells at length disappear, whereas in ascidians they persist. Besides their share in the growth of the mantle, they have an important function as phagocytes. In compound ascidians certain individuals are every now and again perishing, and these dying parts are known to be absorbed by the mantle cells. Also, incoming foreign bodies, such as bacteria, the cells attack and seek to destroy. Numerous bacteria are always present in the mantle of tunicata. Moreover, experiments were made by introducing bacteria through fine glass tubes inserted in the mantle; the mesoderm-cells collected round these tubes, entered them, and fought with the bacteria. Kowalevsky attaches great importance to this function, and supposes the above-mentioned passage of wandering cells to the surface of epithelia to be explained as a means of protection against the intrusion of agents of disease.

MR. L. STEJNEGER gives in the fifteenth volume of the Proceedings of the U. S. National Museum an interesting preliminary description of a new genus and species of blind cave salamander from North America. The discovery of a blind cave salamander in America is regarded by Mr Stejneger as "one of the
